A stand test with the current and voltage which will give losses equal to those in service will determine whether the motor has sufficient capacity to meet the service requirements. In service the temperature of an enclosed motor (§97), well exposed to the draught of air incident to a moving car or locomotive, will be from 75 to 90 per cent (depending upon the character of the service) of the temperature rise obtained on a stand test with the motor completely enclosed and with the same losses. With a ventilated motor (§§98 and 100), the temperature rise in service will be 90 to 100 per cent of the temperature rise obtained on a stand test with the same losses.

441. In making a stand test to determine the temperature rise in a specific service, it is essential in the case of a self-ventilated motor (§100), to run the armature at a speed which corresponds to the schedule speed in service.

In order to obtain this speed it may be necessary, while maintaining the same total armature losses, to change somewhat the ratio between the I^2R and core-loss components.

442. **Calculation for Comparing Motor Capacity with Service Requirements.**— The heating of a motor should be determined, wherever possible, by testing it in service, or with an equivalent duty cycle. When the service or equivalent duty cycle tests are not practicable, the ratings of the motor may be utilized as follows to determine its temperature rise.

443. The motor losses which affect the heating of the windings are, as stated above, those in the windings and in the core. The former are proportional to the square of the current. The latter vary with the voltage and current, according to curves which can be supplied by the manufacturers. The procedure is therefore as follows:

444. (a) Plot a time-current curve and a time-voltage curve for the duty cycle which the motor is to perform, and calculate from these the root mean-square current and the equivalent voltage which with r.m.s. current will produce the average core-loss.

445. (b) If the calculated r.m.s. service current exceeds the continuous rating, when run with average service core-loss and speed, the motor is not sufficiently powerful for the duty cycle contemplated.

446. (c) If the calculated r.m.s. service current does not exceed the continuous rating, when run with average service core-loss and speed, the motor is ordinarily suitable for the service. In some cases, however, it may not have sufficient thermal capacity to avoid excessive temperature rises during the periods of heavy load. In such cases a further calculation is required, the first step of which is to calculate the temperature rise due to the r.m.s. service current, and equivalent voltage.

Let t = temperature rise
$p_0 = I^2R$ loss, kw.
p_c = core-loss, kw.
with r.m.s. service current, and equivalent service voltage.

T = temperature rise
$P_0 = I^2R$ loss, kw.
P_c = core-loss, kw.
with continuous load current corresponding to the equivalent service voltage.

Then

$$t = T\,\frac{p_0 + p_c}{P_0 + P_c}\text{, approximately.}$$

447. (d) The thermal capacity of a motor is approximately measured by a coefficient equal to the ratio of the electrical loss in kw. at its nominal (one-hour) capacity, to the corresponding maximum observable temperature rise.

448. (e) Consider any period of peak load and determine the electrical losses in kilowatt-hours during that period from the *electrical* efficiency curve. Find the excess of the above losses over the losses with r.m.s. service current and equivalent voltage. The excess loss divided by the coefficient of thermal capacity will equal the extra temperature rise due to the peak load. This temperature rise added to that due to the r.m.s. service current, and equivalent voltage, gives the total temperature rise. If the total temperature rise in any such period exceeds the safe limit, the motor is not sufficiently powerful for the service.

449. (f) If the temperature reached due to the peak loads does not exceed the safe limit, the motor may yet be unsuitable for the service, as the peak loads may cause excessive sparking and dangerous mechanical stresses. It is, therefore, necessary to compare the peak loads with the short-period overload capacity. If the peaks are also within the capacity of the motor, it may be considered suitable for the given duty cycle.

APPENDIX II: ILLUMINATION AND PHOTOMETRY*

460. **Luminous Flux** is radiant power evaluated according to its capacity to produce the sensation of light.

461. **The Luminous Intensity** of a point source of light is the solid angular density of the luminous flux emitted by the source in the direction considered; or it is the flux per unit solid angle from that source.

462. **Candle.** — The unit of luminous intensity, maintained by the National Laboratories of France, Great Britain and the United States. This unit, which is used also by many other countries, is frequently referred to as the international candle. The Hefner unit is 0.90 of the international candle.

463. **Candle-Power.** — Luminous intensity expressed in candles.

464. **Lumen.** — The unit of luminous flux, equal to the flux emitted in a unit solid angle (steradian) by a point source of one candle-power.

465. **Illumination** on a surface is the luminous flux-density over that surface, or the flux per unit of intercepting area.

Defining equation: Let E be the illumination and S the area of the intercepting surface. Then

$$E = \frac{dF}{dS} \qquad \text{or, when uniform,} \qquad E = \frac{F}{S}.$$

466. **Lux** is a unit of illumination equal to one lumen per square meter. The C. G. S. unit of illumination is one lumen per square centimeter. For this unit Blondel has proposed the name "Phot." One millilumen per square centimeter (milliphot) is a practical derivative of the C. G. S. system. One foot-candle is one lumen per square foot and is equal to 1.0764 milliphots. The foot-candle is the commonly employed unit of illumination in English-speaking countries.

467. **Exposure.** — The product of an illumination by the time. Blondel has proposed the name "phot-second" for the unit of exposure in the C. G. S. system.

468. **Brightness, *b*, of an Element of a Luminous Surface from a Given Position** is the luminous intensity per unit area of the surface projected on a plane perpendicular to the line of sight, and including only a surface of dimensions negligibly small in comparison with the distance to the observer. It is measured in candles per square centimeter of the projected area.

* Sections 460 to 496, on Illumination and Photometry have been taken from the Publications of the Illuminating Engineering Society, after conference with its Committee on Nomenclature and Standards. (See reports of that Committee.)

Defining equation: Let θ be the angle between the normal to the surface and the line of sight, and dI the luminous intensity of the element. Then

$$b = \frac{dI}{dS \cos \theta}.$$

469. **Normal Brightness, b_0, of an Element of a Surface** (sometimes called **Specific Luminous Intensity**) is the luminous intensity of the element taken normally to the surface of the element, and is expressed in candles per square centimeter.

In practice, the brightness b of a luminous surface, or element thereof, is observed, and not the normal brightness b_0. For surfaces for which the cosine law of emission holds, the quantities b and b_0 are equal.

Defining equation:

$$b_0 = \frac{dI}{dS} \qquad \text{or, when uniform,} \qquad b_0 = \frac{I}{S}.$$

470. **Specific Luminous Radiation.** — The luminous flux density emitted by a surface, or the flux emitted per unit of emissive area. It is expressed in lumens per square centimeter.

Defining equation: Let E' be the specific luminous radiation. Then, for surfaces obeying Lambert's cosine law of emission

$$E' = \pi b_0.$$

471. **Coefficient of Reflection.** — The ratio of the total luminous flux reflected by a surface to the total luminous flux incident upon it. It is a simple numeric. The reflection from a surface may be regular, diffuse or mixed. In perfect regular reflection, all of the flux is reflected from the surface at an angle of reflection equal to the angle of incidence. In perfect diffuse reflection the flux is reflected from the surface in all directions in accordance with Lambert's cosine law. In most practical cases, there is a super-position of regular and diffuse reflection.

472. **Coefficient of Regular Reflection** is the ratio of the luminous flux reflected regularly to the total incident flux.

473. **Coefficient of Diffuse Reflection** is the ratio of the luminous flux reflected diffusely to the total incident flux.

Defining equation: Let m be the coefficient of reflection (regular or diffuse). Then, for any given portion of the surface,

$$m = \frac{E'}{E}.$$

474. **Primary Luminous Standard.** — A recognized standard luminous source reproducible from specifications.

475. **Representative Luminous Standard.** — A standard of luminous intensity adopted as the authoritative custodian of the accepted value of the unit.

476. **Reference Standard.** — A standard calibrated in terms of the unit from either a primary or representative standard and used for the calibration of working standards.

477. **Working Standard.** — Any standardized luminous source for daily use in photometry.

478. **Comparison Lamp.** — A lamp of constant but not necessarily known candle-power against which a working standard and test lamps are successively compared in a photometer.

479. **Test Lamp,** in a photometer, a lamp to be tested.

480. **Performance Curve.** — A curve representing the behavior of a lamp in any particular (candle-power, consumption, etc.) at different periods during its life.

481. **Characteristic Curve.** — A curve expressing a relation between two variable properties of a luminous source, as candle power and volts, candle-power and rate of fuel consumption, etc.

482. **Mean Horizontal Candle-Power** of a lamp. — The average candle-power in the horizontal plane passing through the luminous center of the lamp.

It is here assumed that the lamp (or other light source) is mounted in the usual manner, or, as in the case of an incandescent lamp, with its axis of symmetry vertical.

483. **Mean Spherical Candle-Power** of a lamp. — The average candle-power of a lamp in all directions in space. It is equal to the total luminous flux of the lamp in lumens divided by 4π.

484. **Mean Hemispherical Candle-Power of a lamp** (upper or lower). — The average candle-power of a lamp in the hemisphere considered. It is equal to the total luminous flux emitted by the lamp in that hemisphere divided by 2π.

485. **Mean Zonal Candle-Power** of a lamp. — The average candle-power of a lamp over a given zone. It is equal to the total luminous flux emitted by the lamp in that zone divided by the solid angle of the zone.

486. **The Spherical Reduction-Factor** of a lamp

$$= \frac{\text{mean spherical candle-power}}{\text{mean horizontal candle-power}}.$$

487. **The Spherical Reduction-Factor** should only be used when properly determined for the particular type and characteristics of each lamp. The spherical reduction-factor permits of substantially-accurate comparisons being made between the total lumens, or mean spherical candle-powers of different types of incandescent lamps, and may be used in the absence of proper facilities for direct measurement of the total lumens or mean spherical candle-power.

488. **The Specific Output of Electric Lamps** is properly stated in terms of lumens per watt at lamp terminals. The use of the term efficiency in this connection should be discouraged.

When auxiliary devices are employed in circuit with a lamp, the specific output should be referred to lamp terminals, unless otherwise specified.

489. **The Specific Consumption** of an electric lamp is its watts consumption per lumen. "Watts per candle" is a term used commercially in connection with incandescent lamps, and denotes watts per mean horizontal candle-power.

490. **Photometric Tests** in which the results are stated in candle-power should be made at such a distance from the source of light that the latter may be regarded as practically a point. Where tests are made in the measurement of lamps with reflectors, the results should always be given as "apparent candle-power" at the distance employed, which distance should always be specifically stated.

491. **Basis for Comparison.** — Either the total flux of light in lumens, or the mean spherical candle-power, should always be used as the basis for com-

paring various luminous sources with each other, unless there is a clear understanding or statement to the contrary.

492. Incandescent Lamps, Rating. — It is customary to rate incandescent lamps on the basis of their mean horizontal candle-power; but in comparing incandescent lamps in which the relative distribution of luminous intensity differs, the comparison should be based on their total flux of light measured in lumens, or on their mean spherical candle-power.

493. Life Tests. — Similar filaments may be assumed to operate at the same temperature, only when their lumens per watt consumed are the same. Life tests are comparable only when conducted under similar conditions as to filament temperatures.

494. In Comparing Different Luminous Sources not only should their candle-power be compared, but also their relative form, brightness, distribution of illumination and character of light.

495. Symbols.

Photometric magnitude	Name of unit	Symbols
1. Luminous flux	Lumen	F, Ψ
2. Luminous intensity	Candle	I, Γ
3. Illumination	Phot., foot-candle, lux	E, β
4. Exposure	Phot-second	Et
5. Brightness	Apparent candles per sq. cm. Apparent candles per sq. in.	b
6. Normal brightness	Candles per sq. cm. Candles per sq. in.	b_0
7. Specific luminous radiation	Lumens per sq. cm. Lumens per sq. in.	$E'\beta'$
8. Coefficient of reflection		m

496. In view of the fact that the symbols heretofore proposed conflict in some cases with symbols adopted for electric units by the International Electrotechnical Commission, it is proposed that where the possibility of any confusion exists in the use of electric and photometric symbols, an alternative system of symbols for photometrical quantities should be employed. These should be derived exclusively from the Greek alphabet, for instance:

Luminous intensity .... Γ
Luminous flux .... Ψ
Illumination .... β

STANDARDS IN TELEPHONY AND TELEGRAPHY

TENTATIVE DEFINITIONS *

501. After careful consideration it does not seem that the time is yet ripe for a formal standardization of terms and definitions used in telephony and telegraphy. Many of the terms commonly employed are used in more than a single way, and conversely, many pieces of apparatus and many constants which are essentially identical from a physical standpoint have been and are known by more than one designation.

* Comments or suggestions should be forwarded to the Chairman of the Sub-Committee on Telephone and Telegraph Standards.

502. **Damping of a Circuit.** — The damping, at a given point, in a circuit from which the source of energy has been withdrawn, is the progressive diminution in the effective value of electromotive force and current at that point resulting from the withdrawal of electrical energy.

503. **Damping Constant.** —The damping constant of a circuit is a measure of the ratio of the dissipative to the reactive component of its admittance or impedance.

Applied to the admittance of a condenser or other simple circuit having capacity reactance, the damping constant for a harmonic electromotive force of given frequency is the ratio of the conductance of the condenser or simple circuit at that frequency to twice the capacity of the condenser at the same frequency.

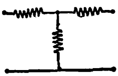
Applied to the reactance of a coil or other simple circuit having inductive reactance, the damping constant for a harmonic current of given frequency is the ratio of the resistance of the coil or circuit at that frequency to twice the inductance at the same frequency.

504. **Equivalent Circuit.** — An equivalent circuit is a simple network of series and shunt impedances, which, at a given frequency, is the approximate electrical equivalent of a complex network at the same frequency and under steady state conditions.

NOTE. — As ordinarily considered, the simple networks, as defined, are the electrical equivalents of complex networks only with respect to definite pairs of terminals, and only as to sending-end impedances, and total attenuation. A further requirement is that the only connections between the pairs of terminals are those through the net-work itself.

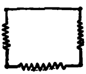
505. **"T" Equivalent Circuit.** — A "T" equivalent circuit is a triple star or "Y" connection of three impedances externally equivalent to a complex network.

Symbol:



506. **"U" Equivalent Circuit.** — A "U" equivalent circuit is a delta connection of three impedances externally equivalent to a complex network. It is also called a "π" equivalent circuit.

Symbol:



IMPEDANCE

507. **Mutual Impedance.** — The mutual impedance, for alternating currents, between a pair of terminals and a second pair of terminals of a network, under any given condition, is the negative vector ratio of the electromotive force produced between either pair of terminals on open circuit to the current flowing between the other pair of terminals.

508. **Self Impedance.** — The self impedance between a pair of terminals of a network, under any given condition, is the vector ratio of the electromotive force applied across the terminals to the current produced between them.

LINE CHARACTERISTICS

509. **Characteristic Impedance.** — Characteristic impedance of a line is the ratio of the applied electromotive force to the resulting steady-state current upon a line of infinite length and uniform structure, or of periodic recurrent structure.

NOTE. — In telephone practice the terms (1) line impedance, (2) surge impedance, (3) iterative impedance, (4) sending-end impedance, (5) initial sending-end impedance, (6) final sending-end impedance, (7) natural impedance and (8) free impedance, have apparently been more or less indefinitely and indiscriminately used as synonyms with what is here defined as "characteristic impedance."

510. **Sending-End Impedance.** — The sending-end impedance of a line is the vector ratio of the applied electromotive force to the resulting steady-state current at the point where the electromotive force is applied.

NOTE. — See note under "Characteristic Impedance." In case the line is of infinite length of uniform structure or of periodic recurrent structure, the sending-end impedance and the characteristic impedance are the same.

511. **Propagation Constant.** — The propagation constant per unit length of a uniform line, or per section of a line of periodic recurrent structure, is the natural logarithm of the vector ratio of the steady-state currents at various points separated by unit length in a uniform line of infinite length, or at successive corresponding points in a line of recurrent structure of infinite length. The ratio is determined by dividing the value of the current at the point nearer the transmitting end by the value of the current at the point more remote.

512. **Attenuation Constant.** — The attenuation constant is the real part of the propagation constant.

513. **Wave-length Constant.** — The wave-length constant is the imaginary part of the propagation constant.

LINE CIRCUITS

514. **Ground-return Circuit.** — A ground-return circuit is a circuit consisting of one or more metallic conductors in parallel, with the circuit completed through the earth.

515. **Metallic Circuit.** — A metallic circuit is a circuit of which the earth forms no part.

516. **Two-wire Circuit.** — A two-wire circuit is a metallic circuit formed by two paralleling conductors insulated from each other.

517. **Superposed Circuit.** — A superposed circuit is an additional circuit obtained from a circuit normally required for another service, and in such a manner that the two services can be given simultaneously without mutual interference.

518. **Phantom Circuit.** — A phantom circuit is a superposed circuit, each side of which consists of the two conductors of a two-wire circuit in parallel.

519. **Side Circuit.** — A side circuit is a two-wire circuit forming one side of a phantom circuit.

520. **Non-phantomed Circuit.** — A non-phantomed circuit is a two-wire circuit which is not arranged for use as the side of a phantom circuit.

521. **Simplexed Circuit.** — A simplexed circuit is a two-wire telephone circuit, arranged for the super-position of a single ground-return signalling circuit operating over the wires in parallel.

NOTE. — In view of the use of the term "Simplex Operation" in telegraph practice, it is felt that the designation "Simplexed Circuit" as applied to the arrangement described is not a happy one.

522. **Composited Circuit.** — A composited circuit is a two-wire telephone circuit, arranged for the super-position on each of its component metallic conductors, of a single independent ground-return signalling circuit.

523. **Quadded or Phantomed Cable.** — A quadded (or phantomed) cable is a cable adapted for the use of phantom circuits.

NOTE. — The type of cable here defined has frequently been designated as "Duplex Cable" — a term which is objectionable, both on account of its lack of description and its widely different use in telegraph practice.

LOADING

524. **Loaded Line.** — A loaded line is one in which the normal inductance of the circuit has been altered for the purpose of increasing its transmission efficiency for one or more frequencies.

525. **Series-loaded Line.** — A series-loaded line is one in which the normal inductance has been altered by inductance serially applied.

526. **Shunt-loaded Line.** — A shunt-loaded line is one in which the normal inductance of the circuit has been altered by inductance applied in shunt across the circuit.

527. **Continuous Loading.** — A continuous loading is a series loading in which the added inductance is uniformly distributed along the conductors.

528. **Coil Loading.** — A coil loading is one in which the normal inductance is altered by the insertion of lumped inductance in the circuit at intervals. This lumped inductance may be applied either in series or in shunt.

NOTE. — As commonly understood, coil loading is a series loading, in which the lumped inductance is applied at uniformly-spaced recurring intervals.

529. **Microphone.** — A contact device designed to have its electrical resistance directly and materially altered by slight differences in mechanical pressure.

530. **Relay.** — A relay is a device by means of which contacts in one circuit are operated under the control of electrical energy in the same or other circuits.

531. **Resonance.** — Resonance of a harmonic alternating current of given frequency, in a simple series circuit, containing resistance, inductance and capacity, is the condition in which the positive reactance of the inductance is numerically equal to the negative reactance of the capacity. Under these conditions the current flow in the circuit with a given electromotive force is a maximum.

532. **Retardation Coil.** — A retardation coil is a reactor (reactance coil) used in a circuit for the purpose of selectively reacting on currents which vary at different rates.

NOTE. — In telephone and telegraph usage the terms "impedance coil," "inductance coil," "choke coil" and "reactance coil" are sometimes used in place of the term "retardation coil."

533. **Skin Effect.** — Skin effect is the phenomenon of the non-uniform distribution of current throughout the cross section of a linear conductor, occasioned by variations in the intensity of the magnetic field due to the current in the conductor.

534. **Telephone Receiver.** — A telephone receiver is an electrically operated device designed to produce sound waves or vibrations which correspond in form to the electromagnetic waves or vibrations actuating it.

535. **Telephone Transmitter.** — A telephone transmitter is a sound-wave or vibration-operated device designed to produce electromagnetic waves or vibrations which correspond in form to the sound waves or vibrations actuating it.

TRANSFORMERS

536. The Coefficient of Coupling of a Transformer. — The coefficient of coupling of a transformer at a given frequency is the vector ratio of the mutual impedance between the primary and secondary of the transformer, to the square root of the product of the self-impedance of the primary and of the secondary.

537. Repeating Coil. — A term used in telephone practice meaning the same as transformer, and ordinarily a transformer of unity ratio.

RADIO*

538. Acoustic Resonance Device. — One which utilizes in its operation mechanical or other resonance to the audio frequency of the received impulses.

539. Antenna. — A system of conductors designed for radiating or absorbing the energy of electromagnetic waves.

540. Atmospheric Absorption. — That portion of the total loss of radiated energy due to atmospheric conductivity.

541. Audio Frequencies. — The normally audible frequencies lying between 20 and about 20,000 cycles per second. (See also Radio Frequencies.)

542. Capacity Coupler. — An apparatus which electrostatically joins portions of two circuits, and thereby permits the transfer of electrical energy between these circuits through the action of electric forces.

543. Coefficient of Coupling. — See §536 above.

544. Conductive Coupler. — An apparatus which magnetically and electrically joins two circuits having a common conductive portion (also known as a Direct Coupler).

545. Counterpoise. — A system of electrical conductors forming one plate of a condenser, the other plate of which is the ground. For alternating current it may be used to replace a direct connection to ground.

546. Damping of a Circuit. — See §502.

547. Damping Factor of a Simple Circuit. — The ratio of the effective resistance of that circuit to twice the effective inductance at any frequency. (The reciprocal of a time.) This term applies only to circuits capable of carrying free alternating currents. (See §503 above.)

548. Detector. — That portion of the receiving apparatus which, connected to a circuit carrying currents of radio-frequency, and in conjunction with a self-contained or separate indicator, translates the radio-frequency energy into a form suitable for operation of the indicator. This translation may be effected either by the conversion of the radio-frequency energy, or by means of the control of local energy by the energy received.

549. Electromagnetic Wave. — A progressive disturbance characterized by the existence on the wave front of electric and magnetic forces acting in directions which are perpendicular to each other and to the direction of propagation of the wave.

550. Forced Alternating Current. — One produced in any circuit by the application of an alternating electromotive force.†

* Sections 538 to 567 have been inserted after conference with the Standards Committee of the Institute of Radio Engineers.

† In power applications termed simply an alternating current.

551. **Free Alternating Current.**—That produced by an isolated electrical displacement in a circuit having capacity, inductance and *less* than the critical resistance.*

552. **Critical Resistance of an Oscillating-current Circuit.**—Twice the square root of the ratio of the inductance of that circuit to the capacity of that circuit both expressed in practical units. This term applies only to circuits capable of carrying free alternating currents.

553. **Group Frequency.**—The number of distinguishable alternating-current groups occurring per second in an electrical circuit.

NOTE 1.—The group referred to above is, in general, mainly a free alternating current which is substantially damped to extinction before the beginning of the following group or train.

NOTE 2.—The acoustic pitch of the note in the receiving station is, in general, determined by the group frequency at the transmitting station.

NOTE 3.—The term "Group Frequency" replaces the term "Spark Frequency."

554. **Inductive Coupler.**—An apparatus which magnetically joins portions of two electric circuits.

555. **Linear Decrement of a Circuit Containing a Resistance Element Equivalent to a Spark.**—The difference of successive current amplitudes in the same direction divided by the larger of these amplitudes. (In circuits containing such an element, not the ratio of successive current amplitudes, but their difference is constant, and characteristic of the damping.)

556. **Logarithmic Decrement.**—Logarithmic decrement of a circuit containing inductance, capacity and constant resistance is one-half the ratio of the electrical energy withdrawn from that circuit during a cycle to the total energy present in that circuit at the beginning of the cycle. It also equals the natural logarithm of the ratio of successive current amplitudes in the *same* direction.

NOTE.—Logarithmic decrements are standard for a complete period or cycle.

557. **Radio Frequencies.**—Those above 20,000 cycles per second. (See also Audio Frequencies.)

NOTE.—It is not implied that radiation cannot be secured at lower frequencies and the distinction from audio frequencies is merely one of definition.

558. **Resonance to an Alternating Current.**—See §531 above.

559. **A Resonance Curve** gives the relation between circuit power, current or voltage at various frequencies of excitation as a function of those frequencies.

560. **A Wave-length Resonance Curve** is one wherein the abscissas are ratios of specified wave lengths to the resonant wave length, and the ordinates are ratios of the energy (or square of the current at corresponding specified wave lengths to the energy (or square of the current) at the resonant wave length. The scale of ordinates and abscissas shall be equal.

561. **A Frequency Resonance Curve.**—One wherein the abscissas are ratios of specified frequencies to the resonant frequency, and the ordinates are ratios of the energy (or square of the current at corresponding specified fre-

* In power applications termed simply an oscillating current. See §5

quencies to the energy (or square of the current) at the resonant frequency. The scales of ordinates and abscissas shall be equal.

562. **A Standard Resonance Curve,** unless otherwise specified, is assumed to be a wave-length resonance curve.

563. **Selecting.** — The process of adjusting an element driven by a plurality of simultaneous impulses until the ratio of desired response to undesired response is a maximum.

564. **Sustained Radiation** consists of electromagnetic waves of constant amplitude (such as are emitted from an antenna in which flows a forced alternating current).

565. **Tuning.** — The process of securing the maximum indications by adjusting the time period of a driven element. (In transmitter or receiver.)

566. **Wave-length Meter.** — A radio-frequency measuring instrument calibrated to read wave lengths.

567. **Rating.** — 1. All radio transmitting sets shall be rated in actual power output measured in the antenna.

NOTE. — The group or audio frequency of the note of the station should be stated as well (except for sustained wave sets, where that characteristic should be mentioned).

2. The over-all efficiency of a radio transmitting station shall be the ratio of the actual power output as measured in the antenna to the power input supplied to the first piece of electrical machinery which is definitely a part of the radio equipment.

STANDARDIZATION RULES AND STANDARD SPECIFICATIONS. — (*See also Standardization Rules of the A.I.E.E.*) During the last decade many of the engineering societies have adopted rules and specifications covering materials, apparatus and methods of procedure. The *Standardization Rules of the American Institute of Electrical Engineers* are given in full in the preceding article. A brief reference to the standardization rules and standard specifications of some of the other engineering societies, with directions for procuring copies of these rules and specifications, are given in this article. A statement of the nature of the publications of the International Electrotechnical Commission and of the Bureau of Standards at Washington is also given.

AMERICAN ELECTRIC RAILWAY ENGINEERING ASSOCIATION. — (*Secretary, E. B. Burritt, 29 West 39th St., New York City.*) This Association issues an *Engineering Manual*, which contains all standards set by the Association, all practices recommended by it, and those practices which, while they have not been formally adopted either as standards or recommended practice, have been discussed and put forward by the Association's various committees. The *Manual* is in loose leaf form and consists of printed matter, drawings and illustrations. The *Manual* is revised each year by the Committee on Standards. The price of the *Manual*, including all sections in a binder, is $4.00 to non-members.

AMERICAN RAILWAY ENGINEERING ASSOCIATION. — (*Secretary, L. H. Fricht, 962, Monadnock Block, Chicago, Ill.*) This Association issues a *Manual* containing the various committee reports which have been formally adopted by the Association. The following items are covered: Roadway; Ballast; Ties; Rail; Track; Buildings; Wooden Bridges and Trestles; Masonry; Signs; Fences and Crossings; Signals and Interlockings; Records and Accounts; Rules and Organization; Water Service; Yards and Terminals; Iron and Steel Structures; Economics of Railway Location; Wood Preservation; Electricity. The cost of the *Manual* is $3.00 to non-members.

AMERICAN SOCIETY OF MECHANICAL ENGINEERS. — (*Secretary, Calvin W. Rice, 29 West 39th St., New York City.*) The Power Test Committee of this Society has under preparation at the present time (1914) a set of *Rules for Conducting Performance Tests of Power Plant Apparatus*, embracing the following subjects: Boilers; * Reciprocating Steam Engines; * Steam Turbines; Complete Steam Power Plants; Pumping Machinery; * Compressors, Blowers and Fans; Locomotives; * Gas Producers; Gas and Oil Engines;* Complete Gas Power Plants; Waterwheels. A preliminary draft of these "Codes" appears in the *Journal* of the Society for November, 1912.

AMERICAN SOCIETY FOR TESTING MATERIALS. — (*Secretary, Edgar Marburg, University of Pennsylvania, Phila., Pa.*) This Society issues every September a *Year Book* which contains all the standard specifications of the Society in their latest revised form. These specifications at present (1914) cover Steel Rails, Structural Steel, Various Steel Objects, Steel Castings, Wrought Iron, Pig Iron, Iron Castings, Locomotive Material, Magnetic Tests of Iron and Steel (*see Magnetic Testing*), Various Kinds of Copper Wire and Wire Bars (*see Wires and Cables, Bare*), Spelter, Manganese Bronze Ingots, Cement, Lime, Clay Products, Preservative Coatings, Road Materials, Timber, Methods of Testing Strength of Materials, and Methods for Metallographic Tests. The price of the *Year Book* is $5.00 to non-members.

* Earlier "Codes" of the Society dealing with these subjects were issued as follows: Boilers, 1899; Steam Engines, 1902; Pumping Engines, 1891; Locomotives, 1894; Gas Engines, 1902.

ELECTRIC POWER CLUB. — (*Secretary, C. W. Roth, 1410 West Adams St., Chicago, Ill.*) This Club is an association of corporations, firms and individuals engaged in the manufacture of electric motors and generators. Its standardization rules, which are printed in a pamphlet entitled *The Electric Power Club*, are confined to sizes of shaft, pulley, etc., speeds, nomenclature, ratings for different kinds of service, and other matters that are industrial in contradistinction to those that are technical or scientific. The pamphlet referred to may be obtained free of charge from the Secretary of the Club.

ILLUMINATING ENGINEERING SOCIETY. — (*Secretary, J. D. Israel, 29 West 39th St., New York City.*) The Committee on Nomenclature and Standards of this Society has drawn up a report of *Proposed Definitions* (*see Trans. Ill. Eng. Soc., Dec., 1912, Vol. 4*). The definitions in this report are substantially the same as those incorporated in the *Standardization Rules of the A.I.E.E.* (1914 edition.)

INSTITUTE OF RADIO ENGINEERS. — (*Secretary, E. J. Simon, 81 New St., New York City.*) See the reports of the Standards Committee of this Institute. Sections 538 to 567 of the *Standardization Rules of the A.I.E.E.* (q.v.) were incorporated in those rules after conference with this Committee.

NATIONAL ELECTRIC LIGHT ASSOCIATION. — (*Secretary, T. C. Martin, 33 West 39th St., New York City.*) In the reports of the annual meetings of this Association are given the recommendations of the various committees dealing with the following subjects: Railway Rates, Transportation, Accounting, Prime Movers, Overhead Line Construction, Lamps, Electrical Apparatus, Meters, Terminology, Grounding Secondaries, Underground Construction, Electrical Measurements and Values, and Street Lighting.

This Association issues, jointly with the **Association of Edison Illuminating Companies** (*Secretary, Geo. C. Holberton, Pacific Gas and Electric Co., San Francisco, Cal.*), a pamphlet entitled *Code for Electricity Meters*. This *Code* deals primarily with the use of watthour meters in connection with the sale of electric energy in both small and large amounts. The following list of chapter headings gives a general idea of the scope of the *Code:* Definitions, Standards and Measuring Instruments, Metering, Specifications for Acceptance of Types of Meters, Specifications for Acceptance of Auxiliary Apparatus, Installation Methods, Methods of Tests, System Tests, Maintenance Methods. The price of the pamphlet is 50 cents.

The N.E.L.A. also issues the *Electrical Meterman's Handbook*, written and compiled by the Committee on Meters. This book is intended primarily for practical meter men, as contrasted with the *Code for Electricity Meters*, which latter is primarily a guide to metering specifications for central station managements and for state and civic commissions. The *Meterman's Handbook* deals with the subject of metering in great detail, containing over 1000 pages. It may be had from the Secretary of the Association for $2.00.

NATIONAL FIRE PROTECTION ASSOCIATION. — This Association issues the *National Electric Code* which contains the rules and requirements of the National Board of Fire Underwriters for electric wiring and apparatus. The *Code* is revised every two years, the next revision being in 1915. A *List of Electrical Fittings* is also issued by the National Board of Fire Underwriters. This is a list of fittings which have been examined and are suitable for the use intended; this list is revised semi-annually. The *Code* and *List of Electrical Fittings* may be obtained free of charge from the National Board of Fire Underwriters, 135 William St., New York City.

OTHER ENGINEERING SOCIETIES.—The reports of the committees of the following societies also contain matter relative to standards of various kinds:

American Electrochemical Society, *Secretary*, J. W. Richards, Lehigh University, South Bethlehem, Pa.

Association of Railway Electrical Engineers, *Secretary*, J. Andreucetti, Room 411, C. & N. W. Terminal Building, Chicago, Ill.

Association of Iron and Steel Electrical Engineers, *Secretary*, W. T. Snyder, McKeesport, Pa.

Electric Vehicle Association of America, *Secretary*, A. J. Marshall, 29 West 39th St., New York City.

Railway Signal Engineers' Association, *Secretary*, C. C. Rosenberg, Times Building, Bethlehem, Pa.

Society of Automobile Engineers, *General Manager*, Coker F. Clarkson, 1790 Broadway, New York City. This society issues a *Handbook* containing the standards recommended for use in the construction of automobiles and automobile accessories.

Among the foreign electrical societies which have issued standards of various kinds may be noted the following:

British Electrical and Allied Manufacturers' Association, King's House, Kingsway, London, W. C., England.

Incorporated Municipal Electrical Association, *Secretary*, C. McArthur Butler, London, England.

Institution of Electrical Engineers, *Secretary*, P. F. Rowell, Victoria Embankment, London, W. C., England.

Verband Deutscher Electrotechniker, *Secretary*, H. Dettmar, Königgratze, Strasse, 106, Berlin, S. W. 11.

INTERNATIONAL ELECTROTECHNICAL COMMISSION. — (*General Secretary's Office, 28 Victoria St., Westminster, London, S. W., England.*) This Commission, which was organized in London in 1906, is made up of National Committees whose membership as a rule is confined to members of the national engineering societies in the several countries. National Committees at present exist in about 25 countries. The United States National Committee, (*Secretary, Dr. A. E. Kennelly, Harvard University, Cambridge, Mass.*) is appointed by the President of the American Institute of Electrical Engineers, and keeps in close touch with the A.I.E.E. Standards Committee. The expenses of the Central Office in London are met by contributions from the various National Committees. In addition to the National Committees there are a number of Special Committees, appointed by the President of the Commission. There are at present Special Committees on Prime Movers, Rating, Nomenclature, and Symbols and Units.

The Commission meets in full session about every two years. The next meeting will be in San Francisco in 1915. These meetings are for the purpose of discussing and acting upon the reports and recommendations of the Special Committees.

The Central Office has, from time to time, published bulletins giving reports of the meetings of the different committees and of the Commission. With the exception of the list of *International Symbols* (*see Symbols and Abbreviations*), no definite standards have yet been published by the Commission. The bulletin containing the list of *International Symbols* may be had of the General Secretary for 2/1 *d*.

BUREAU OF STANDARDS. — The Bureau of Standards at Washington is a branch of the U. S. Department of Commerce. In addition to making tests and comparisons of measuring apparatus, the Bureau carries on numerous

researches related to the establishment and maintenance of the various standards and units of measurement, the development of measuring instruments and methods of measurement, the determination of physical constants and the properties of matter. The results of these investigations are published in pamphlet form, issued in two separate series: (1) *Scientific Papers* and (2) *Technological Papers*. In addition, the Bureau issues from time to time *Circulars* giving useful technical data, standard specifications for apparatus, description of the nature of the standard tests carried out at the Bureau, etc.

A complete list of the publications of the Bureau will be furnished by the Bureau upon request and free of charge; this list is contained in *Circular No. 24* which is brought up to date from time to time. *Circular No. 24* also contains a brief summary of each of the *Scientific* and *Technological Papers*, any one or more of which will also be furnished by the Bureau upon request and free of charge.

The *Bulletin of the Bureau of Standards* is a serial publication in which the *Scientific* and *Technological Papers* are first published, the individual pamphlets referred to above being reprints from the *Bulletin*. Each number of the *Bulletin* contains about 150 pages, the separate numbers being issued as material accumulates, at intervals of about three months. Four numbers constitute a volume. Nine volumes had been issued at the beginning of 1914. The complete *Bulletin* is furnished free to educational and scientific institutions. Individuals may obtain separate numbers in paper covers (current or back numbers) at 25 cents per copy, complete volumes bound in cloth at $1.50 per volume, and may subscribe in advance at the rate of $1.00 per volume to receive the four separate numbers as issued. Orders and payments for the *Bulletin* should be addressed to the Superintendent of Documents, Washington, D. C., and *not* to the Bureau of Standards.

[H. PENDER.]

STARTERS, MOTOR. — (*See also Controllers; Motors, various types of Alternating-Current; Motors, Direct-Current; Rheostats.*) An auxiliary resistance which is used with a motor, either d-c. or a-c., during acceleration is called a starter, or a starting rheostat. A compensator, or induction starter, consists of an auto-transformer and a switch, by the operation of which a reduced voltage is supplied to the terminals of an induction motor for starting.

STARTERS FOR DIRECT-CURRENT MOTORS. — The starters for use with constant speed d-c. motors consist usually of a resistance to be inserted in the armature circuit, this resistance being gradually cut out by the movement of a contact arm over a face plate as the motor comes up to speed. Such rheostats connect the motor field in circuit at the first step and are provided with various safeguards such as low-voltage release, overload release, etc.

Resistance Steps for D-C. Starters. — The resistance is designed to limit the starting current to about 1½ times full load current with enough steps to insure smooth starting. Motors of 10 h.p. or less usually are brought up to speed in about 15 seconds and larger motors in about 30 seconds. Resistors should carry full load current for two minutes, starting cold, with a temperature rise not exceeding 250° C.

Face-plate Type of Starters with Low-voltage Release (Fig. 1). — Fig. 1 shows the connections of a typical d-c. starter used for motors up to 10 h.p. at 110 volts. This starter is provided with a low-voltage release and with an arcing tip at the first contact. The low-voltage release consists of a spring coiled around the pivot of the rheostat arm for returning it to the off-position and an electromagnet for retaining the arm in the on-position as long as the line voltage continues above a predetermined minimum value. The arcing tip at the first contact provides a spring break and thus prevents arcing when the contact arm leaves the first contact in going to the off-position.

For motors larger than 10 h.p. a brush-contact switch is used to short-circuit the starting box when the contact arm is in the running position. A magnetic blow-out may also be used in place of the arcing tip.

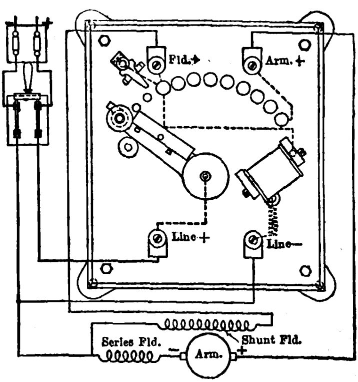


Fig. 1. Starting Box with Low-voltage Release

Overload Release. — This is often furnished, especially with motors of large capacity. This device consists essentially of a solenoid which is connected in series with the motor armature and which, in case of a predetermined overload, opens the circuit of the low-voltage coil. This action releases the contact arm and thus stops the motor.

Mounting of Starting Boxes. — These starting rheostats are frequently mounted on a small panel, together with the line switches and fuses or circuit breaker required for the complete protection of the motor circuit.

Multiple-switch Starters (Fig. 2). — With the larger d-c. motors where the starting conditions are severe the face-plate type of starter is not found satisfactory, so recourse is had to multiple-switch starters. These consist essen-

tially of a number of suitable switches mounted on a panel and a separate resistance, usually of cast-iron grids. The switches are mechanically interlocked so that it is necessary to close them in a given sequence.

The type of starter shown diagrammatically in Fig. 2 is used with 110-volt motors up to 300 h.p. and with 220- and 500-volt motors up to 600 h.p. The first switch on the right of the diagram is provided with magnetic blow-out coils and acts as a circuit breaker. It also has voltage release device. Protection against inadvertently leaving part of the switches open when starting is provided by means of an auxiliary push-button switch that must be held closed until the last switch on the left is closed, thus energizing the coil of the low-voltage release.

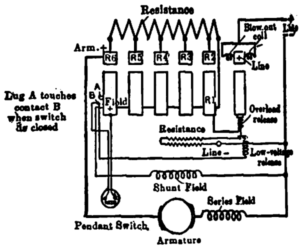

Fig. 2. Connections of Multiple-switch Starter

Starters with Automatically-operated Contactors. — In starting a motor the energy required to overcome the inertia of the motor and the apparatus it is driving must be admitted gradually, which is accomplished by introducing resistance into the armature circuit. If the time taken in starting is too long the resistance may be injured by overheating; if the time is too short the motor may be damaged or the supply circuits seriously disturbed. For these reasons a motor starter that will automatically take care of the proper rate of acceleration presents many advantages. Such a starter can be devised by means of contactor switches and suitable relays, which are operated either by the variation of the voltage drop across a resistance as the motor speeds up, or by the decrease in current which permits a coil to drop its core.

Contactor Starter with Series-relay Control (Fig. 3). — Acceleration by series-relay control is satisfactory where the voltage does not vary more than 12½ per cent either way from a constant value. Fig. 3 shows the connections of a compound-wound motor with a three-switch magnet-switch controller arranged for this type of control of speed acceleration. The relay switch opens when the motor current exceeds a safe value and no further reduction of the starting resistance can be made until the current decreases and allows the relay switch to close.

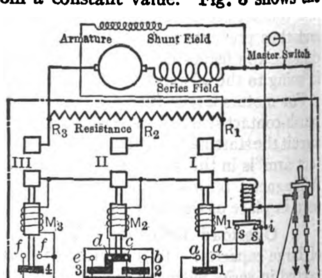

Fig. 3. Diagram of Contractor Starter with Series-relay Control

When the main switch is closed, the closing of the master switch connects coil M_1 across the circuit, thus energizing its core, closing main contacts I and bridging gap a–a by interlocking contact I. The motor starts with all resistance R_3R_1 in series. The high starting current causes the relay switch to open gaps s–s in the control circuit. As soon as the starting current has fallen to a limit predetermined by the relay adjustment the relay core drops, and gap s–s is closed. The second magnet switch then operates, simultaneously closing contacts II, bridging gap b–c by contact 2, and opening gap c–d and closing gap d–e by contact 3.

Contacts II short-circuit resistance R_2R_1, causing an increase in the motor current, and the relay switch again opens gap s–s. But the opening of gap c–d and the closing of gap d–e has, meanwhile, connected coil M_2 across the circuit independently of gap s–s; so that while the relay switch can delay the closing of the magnet switch it has no control over one that is closed. As gaps a–a and b–c are bridged by contacts 1 and 2 respectively, the circuit through coil M_3 will be closed as soon as the motor current has decreased enough to allow the relay switch to drop back and close gap s–s. As soon as the coil m_3 is energized, contacts III are closed, and gap f–f is bridged by contact 4. Contacts III connect the motor directly across the circuit and the bridge across gap f–f removes coil M_3 from any further control by the relay switch.

Contactor Starter with Resistance-drop Control (Fig. 4). — Acceleration by voltage control is applicable where the line voltage does not vary more than 5 per cent either way from a constant value. The arrangement required for this method is given in Fig. 4, which shows the connections of a compound-wound motor with a three-switch magnet-switch controller arranged for speed acceleration by voltage control; that is, the successive operation of the switches depends upon the voltage drop in the starting resistance.

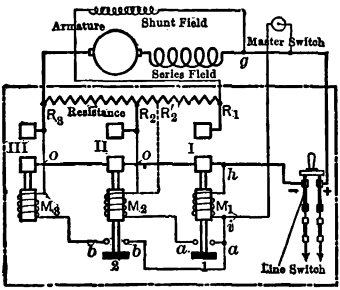

Fig. 4. Diagram of Contactor Starter with Resistance-drop Control

The operation of the controller is started by closing the line switch and the master switch, which connects coil M_1 across the circuit. The core of M_1 rises, main contacts I are closed, and interlocking contacts a–a are bridged by contact I. Main contacts I connect the shunt field directly across the main circuit and close the circuit through the series field, armature and starting resistance R_3R_1. The coils M are wound for full line voltage, except that for higher than 220 volts, 220-volt coils with resistance in series are used. It is evident that the promptness with which the magnet switches act depends largely on the voltage applied to the coil terminals. For example, 180 volts will cause a 220-volt switch to close much more slowly than will the full 220 volts.

When contact I bridges contacts a–a the operating circuit through coil M_2 and resistance R_2R_1 is closed. This coil is then subjected to full line voltage less the drop in resistance R_2R_1. While the starting current is high this voltage drop is considerable, and the closing of the second magnet switch is thereby delayed until the motor current has fallen to a strength that can be approximately predetermined. The operation of the second magnet switch closes contacts II and bridges contacts b–b by contact 2. Contacts II short-circuit resistance R_2R_1 and the bridge across b–b closes the circuit through coil M_3 and resistance R_3R_2. When contacts II close, the starting current increases momentarily and on account of the voltage drop in resistance R_3R_2 the closing of the third magnet switch is delayed in the same manner as described in connection with contacts II.

The lag in the operation of the accelerating magnet switches can be adjusted by changing the connection point of the coils M_2 and M_3 to the resistance. For example, if coil M_2 was connected to the point R_2', as shown by the dotted line, there would be less resistance in series with the coil and consequently a higher voltage would be applied to the coil terminals. The nearer the connection points of the two terminals of coils M_2 and M_3 are to the negative end of the

resistance R_1, the less will be the voltage drop affecting the operation of the second and third magnet switches. If both of these coil terminals were connected to R_1, or to the negative side of the circuit at points *o–o*, coil M_2 would receive the full voltage as soon as contacts *a–a* are bridged and coil M_3 as soon as contacts *b–b* are bridged. The three magnet switches would then close in quick succession, the delay in the operation of the second and third switches being only that caused by their own time element. If no other delaying element is introduced the acceleration will be very rapid, the starting current high and the tax on the motors severe. Acceleration by time element of the switches alone is useful where very quick starting is required.

Contactors for Starters with Acceleration Control. — (*See also Magnets and Solenoids.*) The success of starters with acceleration controls, such as described in the two preceding sections, depends largely on the contactors or contactor switches. Contactors are switches or circuit breakers which are held in the closed position by some auxiliary power, such as a solenoid or compressed air. Contactors of the design shown in Fig. 5 are built in sizes of 100, 250, 350, 500 and 1000 amperes. They consist essentially of a contact that is closed by the action of a solenoid which raises its plunger vertically when the coil is energized and allows it to drop back by gravity, assisted by springs, when the coil is deënergized. The main contacts are above the solenoid and are protected by magnetic blow-out coils so placed on each side of the main contact that the arc is forced quickly to the front and blown out. (*See also Control Systems for Railway Motors.*)

These contactors are ordinarily used in connection with a master switch or controller, and protective relay switches of various kinds to insure the performance of various functions, such as the automatic cutting in and out of resistance in the secondary of an induction motor to maintain constant input to a flywheel set, or any similar features that may be desired.

STARTERS FOR INDUCTION MOTORS may be divided into two classes: (1) those used with motors having a squirrel cage or short-circuited secondary, and (2) those for motors having a wound secondary. In the former case the starting is done by impressing on the primary a voltage sufficient to induce in the short-circuited secondary the current required to develop the proper starting torque, and then transferring the primary connections to full voltage. With induction motors having phase-wound secondaries the method of starting is to connect the primary circuit directly to the line, with the secondary winding short-circuited through a resistance which is cut out in one or more steps.

With squirrel-cage motors up to about 7½ h.p. it is usually feasible to connect the primary immediately to the full line voltage without drawing an abnormal current from the line. With larger squirrel-cage motors this is not feasible, and consequently there have been developed various means of reducing the impressed voltage supplied to the motor.

Starting of Polyphase Motors with Change of Line Connection. — With two-phase motors operated from a two-phase, four-wire system which is

fed from mesh-wound or interconnected generators or transformers, the motor can be thrown on the side circuits, where 71 per cent voltage is available for starting, and can then be thrown over to full voltage for running. With either two-phase or three-phase motors where 50 per cent of line voltage is sufficient for starting and which have two parallel windings per phase, these windings may be connected in series for starting and parallel for running. With three-phase motors that will develop sufficient starting torque on 58 per cent of line voltage and which have their windings suitably designed, these windings may be connected in star for starting and delta for running. All of these methods give only one starting voltage and they usually require a type of winding that is not conducive to the best design of the motor, but they are advantageous in certain cases because they do not require any additional apparatus other than a double-throw switch.

Starting Compensators. — Under normal conditions the most satisfactory means of obtaining the reduced voltage for starting induction motors with squirrel-cage secondaries is by the use of auto-transformers or compensators (q.v.). The auto-transformers supplied for starting induction motors are provided with taps permitting the choice of any one of several voltages. The auto-transformers are designed for starting service only and are not intended to be left permanently in circuit.

Connections of Starting Compensator (Fig. 6). — The connections of the starting compensator for a two-phase motor are shown diagrammatically in Fig. 6, the switching mechanism being omitted for the sake of simplicity. Two auto-transformers are used with a two-phase motor; with a three-phase

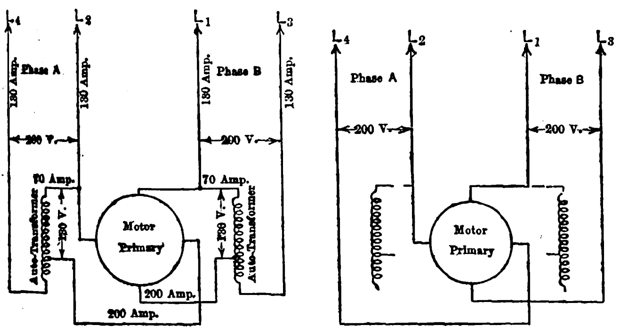

Fig. 6. Connections of Starting Compensator

motor there would be used either three Y-connected or two V-connected auto-transformers. In the starting position the voltage at the motor primary which is connected to the auto-transformer is cut down by the auto-transformers from 200 to 130 in this particular case.

The auto-transformers are provided with taps giving 50, 65 and 80 per cent of line voltage for starting, though it is usually found that the 65 per cent tap gives the proper conditions for average service. With the switch in the running position the auto-transformers are disconnected from the circuit and the motor connected to the full line voltage.

Switch Mechanism. — The switch consists of two sets of butt contacts, copper rods abutting against brass rods, one set of contacts being closed for starting and one for running. When the switch is closed in either direction

coiled springs acting on each pair of rods are compressed so that excellent electrical contact is assured until more than ¼ inch has worn off the end of each rod. The handle of the switch has three positions and locks automatically in the off and running positions but has to be held in the starting position. In starting a motor the handle is first moved very quickly to the starting position and held there until the motor gets up to speed; the handle is then moved quickly past the off position to the running position where it becomes locked. A mechanical device prevents throwing the handle to the switch from the off position to the running position without moving first to the starting position.

Automatic Protection must be secured by means of fuses or circuit breakers in the running leads. If desired, heavier fuses can be installed in the starting leads to give protection against excessive starting currents. A modification of the starting switch is frequently supplied that embodies automatic overload features in the running position, so that no outside protective devices are required. With this type of switch the overload release device consists of two solenoids with plungers, each solenoid being connected in series with a phase of the motor circuit. When the current exceeds a predetermined amount the plunger rises and trips a catch holding the switch in the running position, allowing the switch to open by gravity and disconnect the motor. An oil-filled dash-pot on each solenoid plunger gives an inverse time element feature. The switch contacts trip independently of the handle so that the switch cannot be held closed on an overload.

Resistance Starters for Induction Motors. — With motors having a wound secondary it is customary to connect the primary to full line voltage at starting and to short-circuit the secondary through a resistance. As the motor speeds up, this secondary resistance is cut out in one or more steps until at full speed the secondary is short-circuited. By properly designing the resistors for continuous service instead of for intermittant service, this type of control can be used for speed regulation as well as for starting purposes (*see Controllers*).

With constant-speed induction motors up to 200 h.p. output it is sometimes possible to mount the starting resistance upon the rotor spider, and to control it by butt contact switches operated by a rod which passes through the hollow rotor shaft. By moving this rod out or in by means of a knob at its outer end the resistance may be connected into the secondary circuit for starting or be disconnected therefrom after the motor has come up to speed. With large motors the terminals of the secondary windings are connected by means of slip rings and a drum controller to the resistance, which in this case consists of three resistors mounted separately from the motor. Each resistor has one terminal connected with one of the three phases of the motor secondary. The other terminals of the resistors are connected in star and grounded to the frame of the controller. The drum of the controller short-circuits the various sections of the resistors in steps.

Resistance Steps for Induction Motor Starters. — Wound secondary motors at standstill act as transformers and the resistance in the secondary circuit has to absorb practically the entire input to the motor; as the motor speeds up, the secondary voltage drops off and resistance is cut out of circuit at such a rate that the motor draws from the line about 50 per cent more than full load primary current. Grid resistors for starting service will rise about 250° F. in two minutes. Grid resistors for speed regulation are designed for the same rise on continuous service.

Starters for "Self-starting" Synchronous Motors. — Where self-starting synchronous motors are used they are provided with a squirrel-cage winding on the rotor in addition to the usual field poles and field coils. Owing to this squirrel-cage winding they are started up as induction motors and controlled by

the same type of starting devices. Suitable auxiliary apparatus, such as field rheostats and field switches, must be provided.

CALCULATION OF STEPS FOR RESISTANCE STARTERS.* — (*See also Rheostats.*) Resistance starters usually have from four steps for small motors to seven or ten for large sizes. The number of steps used is commonly somewhat larger than the computed values as a safeguard against excessive starting currents due to improper handling by inexperienced operators. Starters for motors starting under heavy loads are frequently designed with two or three extra steps by which it is permitted to switch the loaded machine on the line with a low current and to raise the current step by step. On the other hand, in stations where experienced operators are available, large motors and synchronous converters are often started on three or four steps.

Calculation for Shunt-motor Starters. — The design is usually based on a fixed maximum current on each step of the starter, as well as on a fixed minimum current for each step. The minimum current must not be taken as less than the load current required for the maximum load with which the motor is to be started.

Let

I_m = the maximum current on each step of the starting rheostat,
I_0 = the lowest current for which the steps are to be designed,
E = the fixed line voltage,
$C = I_m \div I_0$.

Let $K - 1$ be the number of steps required in the rheostat, and let $R_1, R_2, \ldots R_k$ be the total resistances in the circuit, including the resistance of the motor, for the successive positions of the contact arm. K is the number of working contacts over which the contact arm moves, the first contact being when all the resistance of the rheostat is in the circuit and the Kth contact corresponding to all the resistance of the rheostat cut out; whence $R_k = r =$ the motor resistance and $R_1 = E \div I_m$.

It can be shown that the successive resistances form a geometric series with the ratio C, whence

$$K = 1 + \frac{\log\left(\dfrac{E}{rI_m}\right)}{\log C}, \qquad \text{and} \qquad R_1 = \frac{E}{I_m}, \qquad R_2 = \frac{R_1}{C}, \qquad R_3 = \frac{R_2}{C}, \qquad \text{etc.}$$

The value of C must be so chosen that K is a whole number. For most motors which are likely to start under load, the value of C is taken about 1.5. For machines which are started with no load, a larger value for C is usually taken, the limiting value being determined by the ratio of maximum allowable current at starting to current at no load. The maximum allowable current is commonly limited to 1.5 times full-load current. Occasionally twice full-load current is taken, but the lower value is preferable, particularly if both power and lighting services are connected to the same feeders.

Design of Series Motor Starters. — An algebraic method for the computation of the various steps for series-motor starters is rather complicated because the field flux varies with the line current. A graphic method based on equal fluctuations of current on each step of the starting rheostat is as follows.

Let E = the fixed line voltage, I_m the maximum allowable current during starting, and I_0 = the minimum allowable current during starting.

Construct the rectangle AI_mOB as in Fig. 7, in which (AI_m) is the maximum allowable current during starting, and $(OR_1) = E \div I_m$ is the entire resistance

* By O. R. Schurig.

of the circuit when the contact arm of the starter is on the first operating contact. Lay off (AI_0) equal to the minimum current during starting. Determine from the magnetization curve of the machine, at some definite speed the armature voltage E_0 for the current I_0, and the armature voltage E_m for the current I_m at this same speed (*see Motors, Direct-current*). Lay off (OB_0) equal to $(OB) \times \frac{E_0}{E_m}$, and draw the two straight lines (I_mB_0) and (I_0B). Lay off (Or) equal to the resistance of the motor between terminals, and draw (rs) parallel to (OB), and find the point D where (rs) intersects (I_mB_0). Then draw the zig-zag line $I_0v_1Cv_3Fv_5$ . . . If this line does not meet the point D, then the ratio $I_0 \div I_m$ and the corresponding ratio $E_0 \div E_m$ and the distances (AI_0) and (OB_0) must be altered until the new zig-zag line meets the new point D. Then extend the horizontal line Cv_1, Fv_3, . . . until they cut the vertical axis, at R_2, R_3, . . . The resistances of the successive steps (resistances *between* successive contacts) are then equal to the distances (R_1R_2), (R_2R_3), . . .

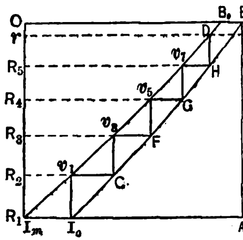

Fig. 7. Graphic Method of Design of Series Motor Starters

For machines working on a straight line magnetization curve, the steps for the starter would be equal, as the line (I_0B) would be parallel to the line (I_mB_0).

Graphic Method for Shunt-motor Starters.—The above method may also be applied to the determination of the steps of a shunt-motor starter, in which case the point B_0 coincides with B.

COST OF MOTOR STARTERS.—The following figures are approximate only and are intended merely to give a rough idea of the cost of some of the common types of starters.

COST OF STARTERS FOR 550-VOLT MOTORS*

Horse-power of motor	1	5	25	100	250
Face-plate type (Fig. 1)	$3.75	$6	$18	$63	....
Multiple-switch type (Fig. 2)	....	....	....	112	$148
Series-relay type (Fig. 3)	....	....	91	115	180
Resistance-drop type (Fig. 4)	....	....	76	110	165
Compensators (Fig. 6)	....	....	59	118	200
Resistance starters for induction motors	....	....	....	221	253
Compensators for "self-starting" synchronous motors	....	....	59	118	200

* Starters for 110- or for 220-volt motors cost about the same as for 550-volt motors.

[S. Q. HAYES.]

STEAM. — (*See also Boilers; Calorimeters, Steam; Pipes and Piping; Steam Engines; Steam Turbines; etc.*) Steam at a given pressure and at a temperature such that any decrease in temperature, the pressure being kept constant, will cause a condensation of water, is said to be "saturated." When the temperature is such that a decrease of temperature, the pressure being kept constant, can take place without the formation of water, the steam is said to be "superheated," and the number of degrees that the temperature can be lowered before the formation of water takes place is called the "degrees of superheat." Saturated steam may contain fine particles of water in the form of spray or mist, in which case the steam is said to be "wet," while if there is no such moisture present the steam is said to be "dry." (When the steam produced by a boiler is wet the steam is also said to be "primed," and the amount of moisture is called the amount of "priming.") Superheated steam is always dry. The weight of the actual (dry) steam in a pound of wet steam (steam and moisture) is called the "quality of the steam." The temperature of saturated steam at a given pressure is the same whether the steam be dry or wet, and is the same as the boiling point of water at that pressure. The temperature of saturated steam, or the boiling point, depends solely upon the pressure of the steam.

TOTAL HEAT OF STEAM. — The amount of heat required to change one pound of water at 32° F. into steam at any pressure, p, is called the "total heat" of the saturated steam at this pressure. The number of B.t.u. required to raise the temperature of one pound of water from 32° to the temperature of the saturated steam at the given pressure is called the "heat of the liquid." The difference between the total heat and the heat of the liquid is called the "heat of evaporation."

In the case of superheated steam, heat is also required to raise the temperature of the steam from the temperature corresponding to saturation to the temperature of the superheated steam. The total number of B.t.u. required to change one pound of water at 32° F. into superheated steam is given in the second table below.

ENTROPY OF STEAM. — (*See also Thermodynamics, Principles of.*) In dealing with steam the change in entropy resulting from adding to one pound of the water at 32° F. an amount of heat necessary to raise its temperature to the boiling point is called the "entropy of the water," the change in entropy during evaporation, i.e., the heat of evaporation divided by the absolute temperature of the boiling point, is called the "entropy of evaporation," and the entropy of the water plus the entropy of evaporation is called the "entropy of the steam." The entropy of the water is approximately the quotient of the heat added to 1 lb. from 32° to the boiling point divided by the average of these two temperatures above absolute zero.

STEAM TABLES. — Tables giving the values of the various properties of steam for the range of temperatures and pressures met with in practice have recently been recomputed by Marks and Davis, using the latest experimental results as the basis for their calculations. The following tables are condensed from those given in their *Steam Tables and Diagrams* (N.Y., 1909).

Saturated Steam. — Using the symbols at top of the table:

Gage pressure in lb. per square in.	$= p - 14.7$
Vacuum, inches of mercury,	$= 29.92 - 2.036\,p$
Entropy of evaporation	$= N - n$
Pounds per cubic foot	$= \dfrac{1}{v}$.

FLOW OF STEAM THROUGH A NOZZLE. — The rate of flow of steam through a nozzle increases as the difference in the pressures on the two sides of the nozzle increases, until the absolute pressure p_0 of the atmosphere into which the nozzle discharges reaches 58 per cent of the initial absolute pressure p of the steam. For greater differences in pressure, i.e., for $\frac{p_0}{p} < 0.58$, the rate of flow through a given nozzle depends only upon the initial absolute pressure of the steam. For $\frac{p_0}{p} < 0.58$ the percentage change in the volume of the steam as it passes through the nozzle also remains constant, the ratio of initial volume to expanded volume being 1.624. The following formulas have been given by the authorities stated for the flow of steam through a nozzle when $\frac{p_0}{p} < 0.58$. The notation is P = initial absolute pressure in pounds per square inch; A = smallest cross section of nozzle in square inches; W = flow in pounds per minute; x = quality of steam $= \frac{100 - y}{100}$ where y is the per cent of moisture; D = superheat in degrees F.

	Dry saturated	Moist	Superheated
Napier	$W = 0.857AP$	$\frac{AP^{0.97}}{x}$	$AP^{0.97}(1 + 0.00065\,D)$
Grashoff	$W = AP^{0.97}$

[WM. KENT.]

STEAM ENGINES. — (*See also Condensers; Power Stations; Steam; Steam Turbines.*) A steam engine is a machine in which the energy of heat is converted into mechanical energy by means of the pressure of steam upon one or more parts of the machine. This article treats of the reciprocating engine only; steam turbines (q.v.) are treated in a separate article.

CLASSIFICATION. — The principal classifications of reciprocating engines are the following:

Single- and Double-acting Engines. — If the steam acts on only one side of the piston it is a single-acting engine; if on both sides, a double-acting.

Throttling and Automatic Engines. — A throttling engine is one in which the speed of the engine is governed by a throttle valve in the steam pipe, used to vary the pressure of the steam admitted to the engine. An automatic cut-off engine is one in which steam is always admitted at full pressure, but is cut off by a valve or valves at different points in the stroke according to the load, the point at which the cut-off takes place being automatically controlled by a governor.

Throttling as a means of governing is seldom employed in other than small engines. It affords a simple and reliable means of speed control for pumps, etc. Automatic regulation of cut-off is capable of closer speed regulation and permits higher ratios of expansion.

Condensing and Noncondensing Engines. — A condensing engine is one in which the steam is exhausted into a condenser, by means of which its pressure is reduced usually to within 1 to 3 pounds per square inch above a perfect vacuum. A non-condensing engine is one whose exhaust steam is discharged at or above atmospheric pressure. Any engine can be operated condensing or noncondensing, but certain minor modifications are usually made in the design of an engine when it is to be operated normally condensing.

Binary-vapor Engine. — This is a very special form of condensing engine. Sulphur dioxide, instead of water, is used as a cooling medium in a surface condenser. The sulphur dioxide in condensing the exhaust steam is itself vaporized and this vapor, under a pressure of about 175 pounds per square inch, is used expansively in a secondary reciprocating engine. The exhausted sulphur dioxide is discharged into a surface condenser in which it is liquefied by cooling water, much the same as in refrigerating practice, and used over and over again. This type of engine has never come into extensive use.

High- and Low-speed Engines. — This classification refers to rotative (fly wheel) speed only; engines having a rotative speed of 150 revolutions per minute or less are usually classified as low-speed engines; when the fly-wheel speed is greater than 150 revolutions per minute the engine is called a high-speed engine. A high-speed engine may have a lower *piston speed* than a low-speed engine; the relation between piston speed and rotative speed depends solely on the length of stroke.

Compound and Multiple-expansion Engines. — A compound engine is one in which the steam is partially expanded in a smaller cylinder and then carried to one or more larger cylinders in which it is further expanded. If the cylinders are in line with each other, using a common piston rod, it is called a tandem compound; if the smaller and larger, or high-pressure and low-pressure, cylinders are side by side it is called a cross-compound. The tandem type is simpler, lighter, cheaper and more compact, and serves well where exact balancing and uniform crank effort are not essential. The cylinders may be vertical or horizontal. Vertical engines take up less floor space, but are more costly than horizontal engines.

An engine in which the total expansion of the steam is divided into three stages, high-, intermediate- and low-pressure, is a triple-expansion engine; if into four stages, a quadruple-expansion engine. Multiple-expansion engines (other than compound) are seldom used for driving electric generators.

Classification According to Valve Gear. — Engines are also classified according to their valve gear (*see Valve Gear, below*), as Corliss engines, slide-valve engines, piston-valve engines and poppet-valve engines.

DESIGN AND CONSTRUCTION. — For a more complete treatment of the design and construction of steam engines see Kent's *Mechanical Engineers' Pocket-Book*. A brief discussion of valves and governors is given below.

Valves and Valve Gear. — Three types of valves are used to control the admission and exhaust of the steam to and from the cylinder, namely the slide valve, Corliss valve and poppet valve.

Slide Valves. — Fig. 1 shows a cylinder with a plain slide valve of the ordinary type. The valve rests in a V-shaped groove in the bottom of the steam chest, and is held up against its seat by pressure of the steam. The valve spindle passes through a channel in the back of the valve, as shown by the transverse section of the cylinder and steam chest, which allows the valve to press against its seat without springing the valve spindle.

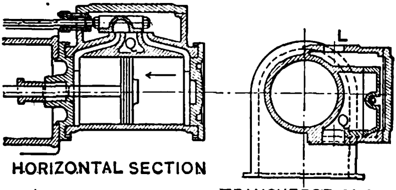

Fig. 1. Plain Slide Valve

In the drawing, the valve is shown moved over to the left so as to allow steam from the steam chest to pass into the head end of the cylinder and force the piston toward the left. Steam from the crank end of the cylinder can flow through a cavity in the valve to the exhaust space Q. Steam enters by the

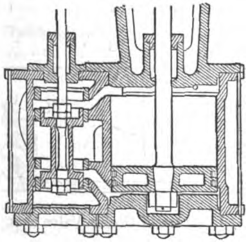

Fig. 2. Piston Valve

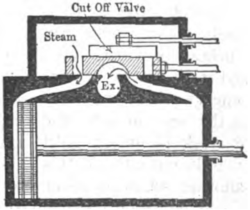

Fig. 3. Riding Cut-off Slide Valve

opening L (transverse section) and escapes through the exhaust space Q. As the piston moves toward the end of the forward stroke, the valve is moved by the eccentric to the right, and it first shuts off the supply of steam from the head end and the exhaust from the crank end of the cylinder, and then opens the supply of steam for the crank end and the exhaust for the head end just before the return stroke is begun.

Other types of slide valves are the piston valve and the riding cut-off valve. In the former, Fig. 2, is used a piston filling an auxiliary cylinder which takes

the place of the steam chest used with the common type. The riding cut-off slide valve, Fig. 3, is essentially a double slide valve. The riding cut-off controls the point of cut-off only, the points of admission, release and compression being controlled by the main valve. (*See Fig. 8 below.*)

Any adjustment of the simple slide valve changes all four events of the stroke, namely admission, cut-off, release and compression. With the riding cut-off slide valve the cut-off can be varied independent of the other events.

Corliss Valve. — To make all four events of the stroke independently adjustable, four separately controlled valves are necessary. One of the first successful four-valve engines was invented by George Corliss in 1848. Various modifications of the original Corliss valve gear have since been made, but the same general principle of operation is embodied in practically all modern four-valve engines.

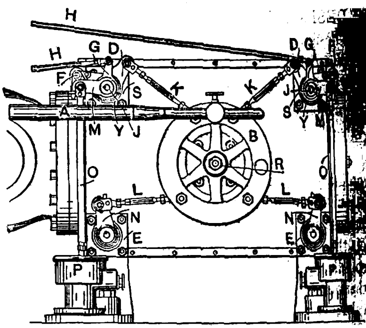

Fig. 4. Corliss Valve Gear

Fig. 4 shows the general external appearance of a simple Corliss valve gear and Fig. 5 is a simplified diagram showing the principle of operation.

"The steam valves work in the chambers *SS*, and the exhaust valves in the chambers *EE*. The double-armed levers *DD* work loosely on the hubs of the steam bonnets; they are connected to the wrist plate *B* by the rods *KK*; the levers *MM* are keyed to the valve stems *JJ*, and are also connected by the rods *OO* to the dashpots *PP*. The double-armed levers *D* carry at their outer ends steam hooks *FF*, these being provided with hardened-steel catch plates which engage with arms *MM*, making the arm *M* and the hook *F* work in unison until steam is to be cut off. At this point another set of levers or cams *GG*, connected by the cam rods *HH* to the governor, come into play, causing the catch plates on the hooks *F* to release the arms *MM*, the outer ends of which are then pulled downwards by the dashpot plunger, causing the steam valves to rotate on their axis and thus cut off steam. The exhaust valve arms *N* are connected to the wrist plate by the rods *LL*; and it is seen that all the valves receive their motion from the wrist plate *B*; the latter receives its motion from the hook rod *A*. This rod is attached to a rocker arm; to this arm the eccentric rod is also attached.

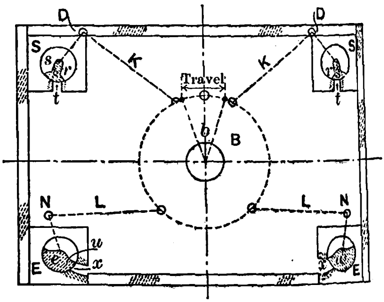

Fig. 5. Diagram of Corliss Valve Gear

"In order to obtain a greater range of cut-off in Corliss engines, a separate steam and exhaust eccentric is used. With two eccentrics the admission and

exhaust valves can be adjusted independently, and steam may be cut off anywhere, nearly to the end of the stroke." (*From Types of Modern Engines and Their Valve Setting, by M. C. Myers, Boston, 1910.*)

Poppet Valves. — This type of valve for engine cylinders is largely used in Europe, but only to a limited extent in this country. Fig. 6 illustrates one type of poppet valve and valve gear, known as the Sulzer valve gear.

Comparison of Different Types of Valves. — Multi-valve engines are more expensive than single-valve types, but give better economy, due to the independent regulation of cut-off and other events of the stroke, and to the reduced requirements of clearance and port space. Rotary valves are more difficult to make and keep steam-tight when used with superheated steam than the poppet and ordinary types. The erosive action and the severe temperature strains caused by superheat add much to the difficulty of maintaining a good valve fit, but the difficulties are minimized in the best designs.

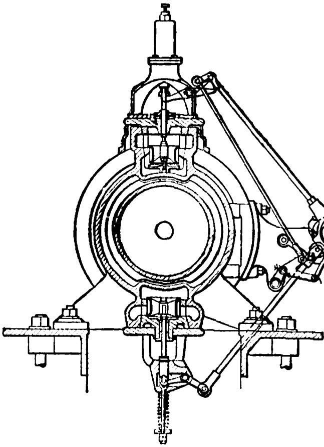

Fig. 6. Sulzer Valve Gear

Governors. — Two types of governors are used, viz., the pendulum or flyball and the flywheel types.

Pendulum Governor.—The construction of the pendulum governor is too well known to need description. This type of governor can be made to control the quantity of steam admitted to the cylinder either by opening or closing a throttle valve, or by varying the point of cut-off. In the latter case a suitable link motion (*see below*) must be provided.

Flywheel or Shaft Governor. — This type of governor is now largely used, especially for high-speed automatic engines.

The Rites governor, Fig. 7, one of the commonest forms of flywheel governors, is of the single-weight or inertia type. The center of gravity of the weight is located approximately at *G*. The governor is shown in position for latest cut-off; the rotation is in the direction of the arrow. Any increase in speed tends to make the center of gravity of the weight seek a position further away from the center of the shaft and causes the weight to swing on its pivot in a direction opposite to that of the wheel; the eccentric is attached to the weight, and this movement brings the center of the eccentric nearer the center of the shaft, and increases its angular advance, thus effecting an earlier cut-off.

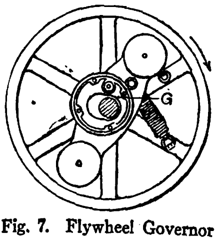

Fig. 7. Flywheel Governor

This and other types of shaft governors are described in detail in a small book on *Shaft Governors* (*Hill Pub. Co., 1908*).

Link Motion. — Link motions, of which the Stephenson link is the most commonly used, are designed for two purposes: first, for reversing the motion of the engine, and second, for varying the point of cut-off by varying the travel

of the valve. The Stephenson link motion is a combination of two eccentrics, called forward and back eccentrics, with a link connecting the extremities of the eccentric rods, so that by varying the position of the link the valve rod may be put in direct connection with either eccentric or may be given a movement controlled in part by one and in part by the other eccentric. When the link is moved by the reversing lever into a position such that the block to which the valve rod is attached is at either end of the link, the valve receives its maximum travel, and when the link is in mid-gear the travel is the least and cut-off takes place early in the stroke.

DEFINITIONS PERTAINING TO RATING AND PERFORMANCE OF STEAM ENGINES. — The following terms are commonly employed.

Indicated Horse-power. — The indicated horse-power P of an engine is found by the formula

$$P = \frac{pLAN}{33,000},$$

in which p is the mean effective pressure, in pounds per square inch, as found by an indicator (*see below*), L the length of the stroke in feet, A the area of the piston in square inches (corrected for area of the piston rod), N the number of single strokes per minute, equal to the number of revolutions of a single-acting, or twice the number of revolutions of a double-acting engine.

Brake Horse-power. — The brake horse-power of an engine is the power delivered by its shaft as determined by a dynamometer or Prony brake. It is equal to the indicated horse-power minus the power absorbed in friction of the engine. In well-designed engines working under normal loads the friction is usually from 8 to 12 per cent of the indicated power; the total power absorbed in friction is nearly a constant at all loads, so that its percentage increases to 100 as the load decreases to zero, when the whole of the indicated horse-power is absorbed in overcoming friction.

Rated Horse-power. — When an engine is commercially rated at a certain horse-power it is understood that it will deliver that power when run under those conditions for which it is designed, such as speed, steam pressure, back pressure, etc., and cutting off at that fraction of the stroke which will give its best economy. Its rated overload capacity is the power it will deliver with the same speed, steam pressure and back pressure, and cutting off at the latest point which the design of the valve motion will permit.

Indicator Diagram. — An indicator diagram is a diagram (see Fig. 8), showing the steam pressure in the engine cylinder at each point of the stroke. Such a diagram may be actually obtained by means of a steam-engine indicator, which is an instrument which causes a pencil to record on paper the pressure in the cylinder at every point of the stroke. The diagram drawn by the pencil shows whether the valves are properly adjusted, and it is also used in figuring the power developed in the cylinder, and approximately the steam consumption. A diagram of a noncondensing engine in which the steam is cut off at about one-quarter of the stroke is shown in Fig. 8.

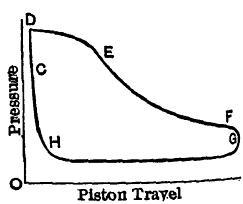

Fig. 8. Indicator Diagram of Simple Engine

The lines and points have the following significance.

Point of Admission, C, is the point at which the steam valve opens.

Admission Line, *CD,* shows the rise of pressure due to the admission of steam to the cylinder by opening the steam valve.

Steam Line, *DE,* is drawn when the steam valve is open and steam is being admitted tc the cylinder.

Point of Cut-off, *E,* is the point where the admission of steam is stopped by the closing of the valve. It is often difficult to determine the exact point at which the cut-off takes place. It is usually located where the outline of the diagram changes its curvature from convex to concave.

Expansion Curve, *EF,* shows the fall in pressure as the steam in the cylinder expands doing work.

Point of Release, *F,* shows when the exhaust valve opens.

Exhaust Line, *FG,* represents the change in pressure that takes place when the exhaust valve opens.

Back-pressure Line, *GH,* shows the pressure against which the piston acts during its return stroke.

Point of Exhaust Closure, *H,* is the point where the exhaust valve closes. It cannot be located definitely, as the change in pressure is at first due to the gradual closing of the valve.

Compression Curve, *HC,* shows the rise in pressure due to the compression of the steam remaining in the cylinder after the exhaust valve has closed.

Initial Pressure is the pressure acting on the piston at the beginning of the stroke.

Terminal Pressure is the pressure above the line of perfect vacuum that would exist at the end of the stroke if the steam had not been released earlier. It is found by continuing the expansion curve to the end of the diagram.

Other Definitions. — In addition to the terms defined above, the following are commonly employed:

Throttle Pressure is the pressure in the steam pipe at the entrance to the throttle valve.

Mean Effective Pressure is that equivalent constant pressure which will do the same amount of work on the piston per stroke as is done by the varying pressure shown by the indicator card. This may be calculated by dividing the area of the card by the length and multiplying by the scale of the spring used in the indicator.

Clearance. — The portion of the cylinder volume, including the steam ports, not swept through by the piston but which is nevertheless filled with steam when admission occurs is called the clearance volume. It ranges from 1 per cent of the piston displacement in very large engines to 10 per cent or more in small high-speed engines.

Ratio of Expansion is the ratio of the piston displacement (in low-pressure cylinder in case of a multiple-expansion engine) to the volume of the steam admitted through the throttle valve at each stroke (or half stroke in case of a double-acting engine), the volume being that corresponding to the pressure on the engine side of the throttle valve.

Wire Drawing, as applied to steam, is the reducing of its pressure, due to its flowing through restricted pipes and passages.

EFFICIENCY OF A STEAM ENGINE. — By the thermal efficiency of a steam engine is meant the quotient of the B.t.u. per hour equivalent to the

indicated horse-power divided by the total number of B.t.u. in the steam supplied per hour; or, putting

W = pounds of steam supplied per hour per indicated horse-power,

x = quality of the steam supplied (= lb. of dry steam per lb. of wet steam; see article on *Steam*),

L = heat of evaporation per pound of steam at throttle pressure, in B.t.u. per pound,

h = heat of the liquid at throttle pressure, B.t.u. per pound,

h_e = heat of the liquid of feed water, B.t.u. per pound, taken at the temperature corresponding to the pressure in the exhaust pipe near the engine. (*See A.S.M.E. code, 1913.*)

Then the thermal efficiency for saturated steam is

$$E_t = \frac{2546.5}{W\,(xL + h - h_e)}.$$

If the steam is superheated, let

H = total heat of superheated steam at throttle pressure and degree of superheat, in B.t.u. per pound.

Then the thermal efficiency is

$$E_t = \frac{2546.5}{W\,(H - h_e)}.$$

The above formulas are also applicable to the calculation of the over-all efficiency, including friction losses, if W is taken as the pounds of steam supplied per hour per brake horse-power.

Efficiency of Rankine Cycle. — The maximum possible thermal efficiency is that of an engine performing the ideal Carnot's cycle (*see Thermodynamics, Principles of*), but this cycle is not very closely simulated by ordinary engines, even when the losses are neglected. Instead the efficiency of the "Rankine cycle" is employed as a standard of reference. This is an ideal cycle which assumes that the work done by the engine is equal to the "maximum work" (*see Thermodynamics*) corresponding to an adiabatic expansion from throttle pressure to exhaust pressure and an isothermal condensation of the exhaust steam and a compression of the condensed water to throttle pressure.

Rankine Efficiency for Dry Saturated Steam. — Let

H_1 = total heat, B.t.u. per pound, of dry saturated steam at throttle pressure,

H_2 = total heat, B.t.u. per pound, of dry saturated steam at exhaust pressure,

h_2 = heat of the liquid, B.t.u. per pound, at exhaust temperature,

T_2 = temperature of exhaust steam, in °F.,

N_1 = total entropy of 1 pound of dry saturated steam at throttle pressure,

N_2 = total entropy of 1 pound of dry saturated steam at exhaust pressure.

Then the efficiency is

$$E_r = \frac{H_1 - H_2 + T_2\,(N_2 - N_1)}{H_1 - h_2}.$$

Rankine Efficiency for Wet Steam. — In addition to the above symbols let

H_w = total heat, B.t.u. per pound, of wet steam at throttle pressure,

N_w = total entropy of 1 pound of wet steam at throttle pressure,

T_1 = temperature of steam at throttle pressure, in °F.

Then the efficiency is

$$E_r = \frac{H_1 - H_2 + T_2\,(N_2 - N_1) - (N_1 - N_w)\,(T_1 - T_2)}{H_w - h_2}.$$

Rankine Efficiency for Superheated Steam. — In addition to the above symbols let

H_s = total heat, B.t.u. per pound, of superheated steam at throttle pressure,
N_s = total entropy of 1 pound of superheated steam at the given degree of superheat at throttle,
t_s = degree of superheat at throttle, in °F.

Then the efficiency is

$$E_r = \frac{H_1 - H_2 + T_2 (N_2 - N_1) + (T_1 + 0.5\, t_s - T_2)(N_s - N_1)}{H_s - h_2}.$$

Efficiency Ratio Referred to the Rankine Cycle. — This is the ratio of the actual efficiency of the engine (referred to the indicated horse-power) to the efficiency of the Rankine cycle (using dry steam) working between the same limits of pressure, i.e.,

$$\text{Eff. Ratio} = \frac{E_t}{E_r}.$$

STEAM ENGINE EFFICIENCIES—SATURATED STEAM.

The actual thermal efficiencies of multiple expansion engines using superheated steam range from about 19 to 23 per cent.

Engine Losses. — The actual efficiencies of steam engines are necessarily much lower than the efficiency of the Rankine cycle due to the thermal and mechanical losses. These losses consist chiefly of (1) cylinder condensation, (2) steam leakage, (3) incomplete expansion and compression on return stroke, (4) friction, (5) clearance loss, (6) radiation and (7) the admission of wet steam.

Cylinder Condensation is due to the chilling of steam by the cooler cylinder walls during admission and early expansion, thus reducing the active heat during expansion. Condensation increases with the range of expansion per cylinder and with the duration of the cycle. The condensation loss is

augmented by the formation of a water film on the cylinder walls. It is successfully reduced by expanding the steam in several stages, thus reducing the range of temperature in each cylinder and rendering the heat carried to the exhaust in that cylinder available in succeeding cylinders. Other remedies for condensation are: increasing the rotative speed; steam jackets about the cylinders; and reheaters to dry the steam between cylinders. The most positive and effective remedy is superheat sufficient to keep the steam dry at least during admission.

Steam Leakage past valves, pistons and packing increases with the pressure difference. It is an important element of loss in all piston engines and tends to increase with the wear of moving parts. Leakage is especially serious in cylinders employing a wide range of pressures. Flow of steam through orifices, in pounds, increases directly as the pressure (Napier's rule), and through pipes as $\sqrt{\text{density}}$. (*p. 845* Kent's *Mechanical Engineers' Pocket-Book.*)

Incomplete Expansion and Compression. — As a rule the release occurs before the piston reaches the end of the stroke and the point of closure comes before the piston reaches the end of the back stroke. There is a consequent loss of expansion on the forward stroke. The piston also has to do work in compressing the steam remaining in the cylinder on the reverse stroke. These two features are, as a rule, necessary; the first to reduce cylinder condensation, and the second for its cushioning effect. The first always, and the second usually, results in a net loss.

Friction varies with the type and condition of the engine, is greater in compound engines than in simple engines, and is nearly independent of the load, increasing but slightly as the load increases. It ranges from 4 to 20 per cent of the rated output.

Losses Due to Radiation, Clearance and Moisture. — With well-lagged cylinders radiation losses are small. Some clearance is necessary in every engine, but the amount is much greater for high speeds than for low speeds. The loss due to it is trifling in slow-speed engines of long stroke. Moisture dilutes the steam admitted but has little effect on the consumption of *dry* steam; the consumption of the fluid (steam and moisture) is of course increased in proportion to the percentage of moisture present.

ECONOMY OF STEAM ENGINES.* — The performance of a steam engine is frequently expressed in terms of the number of pounds of steam per hour required per indicated horse-power, per brake horse-power or per kilowatt (if used to drive an electric generator). The number of pounds of steam per unit of output is called the "economy" of the engine or of the combined engine and generator unit.

Such data may be very misleading unless comparisons are based on identical conditions of steam pressure, superheat, vacuum, etc. A true measure of economy applicable to all conditions may be expressed in net heat units consumed per unit of output, as B.t.u. per kilowatt-hour. In such determinations of economy all heat returned from the exhaust to the boiler should be credited to the engine or turbine.

The commonest means of gaining good engine economy are: raising the initial pressure, compounding, condensing and superheating.

Effect of Steam Pressure on Economy and Capacity. — There can be no universal rule connecting initial pressure and working economy. Compound

* Adapted from lecture notes of Prof. W. E. Wickenden.

engines are better adapted to high pressures than simple engines. Experience indicates that the following gauge pressures are desirable:

Simple, condensing engine without steam jackets	60 lb.
Simple, condensing engine with steam jackets........	80 lb.
Simple, non-condensing engine without steam jackets .	100 lb.
Compound, non-condensing engines	175 lb.
Compound, condensing engines	150 lb.
Triple-expansion, condensing engines	175 to 200 lb.
Quadruple-expansion condensing engines	200 lb.

An important advantage from the use of high pressures is the greater capacity which can be developed from a given engine. The ratio of pressure and capacity is nearly a direct one. High pressures tend to improve economy but not to the extent theoretically available, due to the counteracting effects of condensation and steam leakage with increasing pressure ranges. High steam pressures, however, usually add to the expense of piping and its maintenance. From an examination of a large number of engine performances Stevens and Hobart give the general relation of pressure and economy as shown in Fig. 9.

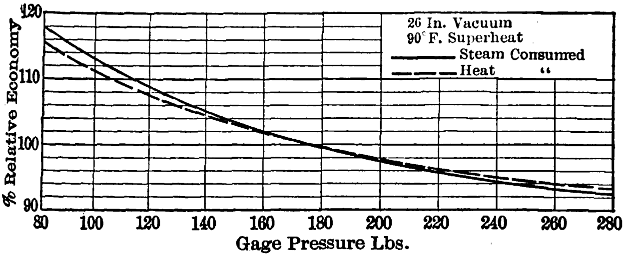

Fig. 9. Effect of Steam Pressure on Economy of Compound Piston Engines

Effect of Multiple Expansion on Economy. — The loss due to cylinder condensation increases with an increase of the difference of temperature of the steam during admission and exhaust, and therefore tends to become greater as the initial pressure is higher. By dividing the total range of expansion into two or more stages, the range of temperature in any one cylinder is decreased, and this lessens the total loss due to cylinder condensation.

Triple and quadruple expansion afford substantial economies with constant load as in pumping and marine service, but have little advantage with the variable loads of electric service to compensate for their great weight, complexity, bulk and cost. Compound engines with high cylinder ratios permit more complete expansion, but have less overload capacity than engines of smaller ratios. For electric service more than 18 expansions is seldom profitable. A cylinder ratio of 1 : 2.5 is well adapted to a pressure of 100 pounds; 1 : 3 to 125 pounds; 1 : 3.5 to 150 pounds and 1 : 4 to 175 pounds or above. Compound engines are relatively uneconomical at light loads, but have a greater economical range of overloads than simple engines. Compound engines, with a moderate cylinder ratio, usually give their best economy at ¼ cut-off in the high-pressure cylinder and will safely carry an overload of 50 per cent.

Effect of Condensing on Economy. — Condensing serves to increase both the capacity and economy of engines. The theoretical gain from condensing to various back pressures is indicated in Fig. 10. Actual engines can avail themselves of but a part of this gain, the proportion falling as the vacuum is increased due to the added condensation and leakage. Expansion to very

low pressures requires cylinders of excessive volume. Condensing equipment, especially that for high vacuum, adds much to the first cost of a plant and hence

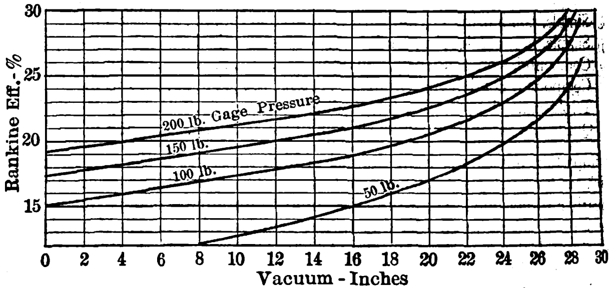

Fig. 10. Effect of Vacuum on Theoretical Efficiency

to its burden of fixed charges. (*See article on Condensers.*) Condensers require from one to three pumps and the thermal gain is reduced by the amount of their heat consumption. The temperature of the exhaust steam is lowered as the vacuum increases and so reduces the heat which can be reclaimed in the feed water. It is of great importance that the net gain rather than the apparent gain be considered in determining the economics of various vacua. Reduced steam consumption lessens the necessary investment in steam-generating equipment and piping, and this tends to somewhat counterbalance the investment in condensing apparatus. (*See article on Power Stations.*)

Effect of Superheating on Economy. — Superheating the steam is more effective than using steam jackets and reheaters as a preventive of cylinder condensation under the usual central-station conditions. With proper valve structures there is a decided net saving in heat consumption as the superheat is increased within reasonable limits, but this procedure usually adds to the

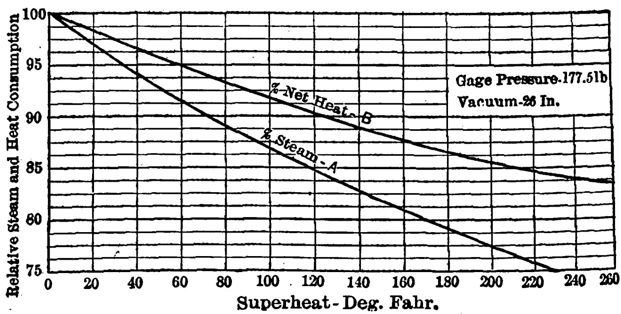

Fig. 11. Effect of Superheat on Piston-engine Economy

cost of piping, fittings and their upkeep. Stevens and Hobart report the mean relationship between superheat and economy in compound and multiple expansion engines, as shown in Fig. 11. It is especially important that economic comparison be based on the heat unit consumption as in Curve B. Additional advantages from superheating are the reduction of condensation, radiation losses and pressure drop in steam pipes.

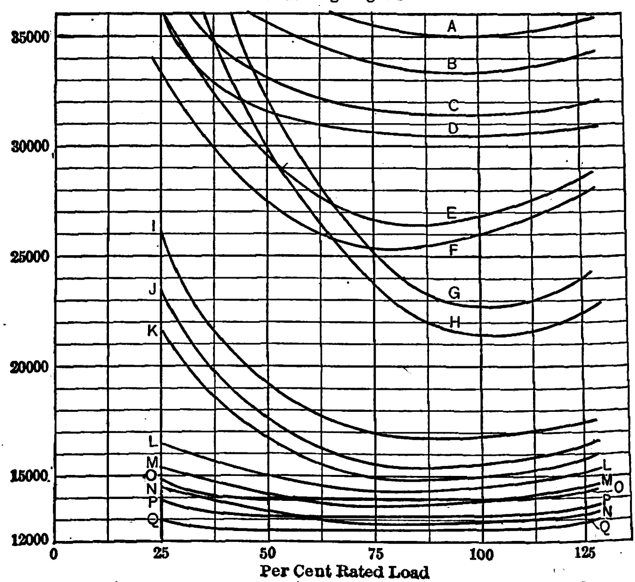
Fig. 15. Steam Consumption 4 Corliss and Grid-iron Valve Compound Condensing Engines



Per Cent Rated Load

Fig. 16. Engine Performance in B.t.u. per Indicated Horse-power-hour

Variation of Economy with Load. — Other factors affecting the economy of engines are the size of the unit, the speed, the mode of governing and the uniformity of load. Stevens and Hobart give the relations between engine sizes, loads and economy shown in Fig. 12 as averages for compound piston engines. Simple engines as a rule show smaller variation in economy with partial loads than compound engines. Typical economy curves for simple and compound engines with saturated steam and compound engines with superheated steam are shown in Figs. 13 to 16. The curves in Fig. 16 correspond to like lettered curves in the other figures.

Economy of the Binary-vapor Engine. — With this type of engine there has been obtained an economy of only 8.36 pounds of steam per indicated horse-power-hour, corresponding to a heat consumption of 158.3 B.t.u. per minute. This was the best recorded performance in steam-engine practice at the time of the report (1907) and has not been noticeably exceeded since (1913).

DIMENSIONS AND WEIGHT OF ENGINES depend so largely upon the type, speed, etc., that it is impossible to give representative figures in the space available. The following table from the *Elec. World*, (*Sept.*, *1902*), gives the dimensions of some very large engines in New York City.

DIMENSIONS OF SOME LARGE RECIPROCATING ENGINES

Name of station	Metropolitan	Manhattan	Kingsbridge	Rapid Transit	Edison
Type of engine	Vert. cross-comp.	Double 2 hor. 2 vert. cyls.	Vert. cross-comp.	Double, 2 hor. 2 vert. cyls.	3-cyl. vert.
Rated horse-power	4500	8000	4500	8900	5200
Cylinders, all 60-in. stroke, in.	46, 86	44, 88	46, 86	42, 86	43½, 2-75½
Piston rods, diam., in.	9, 10	8	9, 10	8, 10	9
Crank pins, in.	14×14	18×18	14×14	20×18	22 & 16×14
Wrist pins, in.	14×14	12×12	14×14	12×12	14×14
Shaft length	27 ft. 4 in.	25 ft. 3 in.	27 ft.	25 ft. 3 in.	35 ft.
max. diam.	37 in.	37 in.	39 in.	37 in.	29⅜ in.
bearings, in.	34×60	34×60	34×60	34×60	26×60

The shafts are hollow, with a 16-inch hole, except the Edison which have a 10-inch hole. The speed of all the engines is 75 revolutions per minute, or 750 feet per minute. The crank pins of the Manhattan and Rapid Transit engines are each attached to two connecting rods, side by side, horizontal and vertical, each rod having a bearing 9 inches long on the pin. The crank pins of the Edison engine are 16 inches in diameter for the side cranks, and 22 inches for the center crank.

TESTING OF STEAM ENGINES. — The actual work done by an engine may be tested by a brake or friction dynamometer, or in the case of engines driving electric generators by measuring the electric energy delivered, correction being made for the efficiency of the generator. The work done in the cylinder is obtained by taking numerous indicator diagrams and calculating

from them the mean effective pressure and the horse-power. The steam consumption is tested by condensing all the steam discharged by the engine and weighing the water of condensation. When a condenser is not available the feed water delivered to the boilers may be weighed instead, precautions being taken to insure that all of the steam made by the boiler is used by the engine. Full directions for making steam-engine tests will be found in the "Code of 1902" in *Trans. A.S.M.E.*, of that year, and reprinted by the Society in a pamphlet of 78 pages. For a condensed abstract of the Code see Kent's *Mechanical Engineers' Pocket-Book, p. 988.* (A revised Code will probably be printed in 1914.)

Plant Tests. — In the introduction to the report above referred to the Committee says:

The heat consumption of a steam-engine plant is ascertained by measuring the quantity of steam consumed by the plant, calculating the total heat of the entire quantity, and crediting this total with that portion of the heat rejected by the plant which is utilized and returned to the boiler. The term "engine plant" as here used should include the entire equipment of the steam plant which is concerned in the production of the power, embracing the main cylinder or cylinders; the jackets and reheaters; the air, circulating, and boiler-feed pumps, if steam driven; and any other steam-driven mechanism or auxiliaries necessary to the working of the engine. It is obligatory to thus charge the engine with the steam used by necessary auxiliaries in determining the plant economy, for the reason that it is itself finally benefited, or should be so benefited, by the heat which they return, it being generally agreed that exhaust steam from such auxiliaries should be passed through a feed-water heater, and the heat thereby carried back to the boiler and saved.

SPECIFICATIONS. — (*See also article on Specifications.*) In obtaining bids for steam engines the prospective purchaser or his engineer usually furnishes only general specifications, stating the kind of work to be done by the engine, such as driving a cotton mill, or an electric power plant, and the following requirements: (1) Indicated horse-power required, (*a*) Maximum, (*b*) Average; (2) Steam pressure available at engine; (3) Maximum absolute back pressure; (4) Number of revolutions; (5) Required steam consumption.

The bidders then furnish with their bids complete detailed specifications with guarantees of the engines they propose to supply, with drawings, when these are required. The bidders are usually prepared to contract for the installation, erection and starting of the engine, especially if it is of a large size.

FOUNDATIONS FOR STEAM ENGINES. — Engine foundations may be built of brick or concrete; the latter is more commonly employed in modern practice. The concrete is made with proportions of one barrel of Portland cement, three of sand, and five of crushed stone.

If the foundation is to be of concrete a wooden box is built in the ground, the inside of the box being the shape of the foundation. Over the top of this box are a number of pieces of joist, from which the anchor bolts or holding-down bolts are hung. Most engine builders furnish drawings giving location of foundation bolts and size of foundation required. The nuts at the top of these bolts are blocked up to the height they are to be when the engine is in place.

The heads of the bolts are at the bottom. A cast-iron plate, eight inches by eight inches by one inch, with a square recess for the bolt head, is at the bottom of each rod. Around each bolt a piece of four-inch galvanized-iron gutter pipe is placed, and the top end of the pipe stuffed with waste to keep the mason from dropping cement into the space between the pipe and the bolt. The concrete is now dumped in and tamped down. After it has set, the wooden joists holding the bolts may be taken away.

The engine is next put over the foundation and supported on iron bars one-half inch square or perhaps larger, these bars being placed near the bolts. By means of wedges, etc., the engine is leveled; the main shaft is placed parallel with the shafting which it is to drive. The bolts are next tightened fairly tight. As it is impossible to core the holes in the engine bed exactly as called for on the drawing, the leeway given by the space between the bolts and the iron pipe surrounding it takes care of variations of from an inch to an inch and a half.

A wall of putty, sand, or cement about one inch high is built about one inch from the engine bed. A thin, neat Portland cement, mixed to the consistency of a thick cream, is poured under the engine bed and serves to fill the space around the bolts and to give the bottom of the bed a perfect bearing over the entire foundation. Before the cement becomes hard, the edge may be trimmed up nicely by means of a trowel; the bolts are then tightened again.

Sometimes type metal instead of cement is poured under the engine bed.

OPERATION. — Full directions for setting the valves of a steam engine will be found in a little book by M. C. Myers, entitled *Types of Modern Engines and Their Valve Setting* (Boston, 1910). Other useful data on the operation and performance of steam engines will be found in a book published by the Crosby Steam Gauge and Valve Co., entitled *Steam Engine Indicator*. See also the more elaborate treatises listed in the bibliography below.

Speed Control. — The speed of an engine can always be controlled by changing the opening of the throttle valve, but this method is usually wasteful. A more efficient method is to change the point of cut-off. This can be done while the engine is running by using a suitable link motion (*see above*), or by changing the setting of the governor spring if the governor is of the "automatic" type. On engines driving alternators in parallel this is usually accomplished by having an electric motor arranged to act directly on the governor spring so that the tension of the spring may be controlled from the switch-board.

Equalizing Variable Load by Storing Heat in Hot Water. — There is no satisfactory method for equalizing the load on the engines and boilers in electric-light stations. Storage batteries have been used, but they are expensive in first cost, repairs and attention. Mr. Halpin, of London, proposes to store heat during the day in specially constructed reservoirs. As the water in the boilers is raised to 250 pounds pressure, it is conducted to cylindrical reservoirs resembling English horizontal boilers, and stored there for use when wanted. In this way a comparatively small boiler-plant can be used for heating the water to 250 pounds pressure all through the twenty-four hours of the day, and the stored water may be drawn on at any time, according to the magnitude of the demand. The steam engines are to be worked by the steam generated by the release of pressure from this water, and the valves are to be arranged in such a way that the steam shall work at 130 pounds pressure. A reservoir 8 feet in diameter and 30 feet long, containing 84,000 pounds of heated water at 250 pounds pressure, would supply 5150 pounds of steam at 130 pounds pressure. At a steam consumption of 18 pounds per horse-power-hour, such a reservoir would supply 286 effective horse-power-hours.

COST OF STEAM ENGINES. — The price of steam engines varies not only with their size and weight, but also with their style, design and workmanship. When builders are asked to submit bids for the same rated power of engine, with the same steam pressure and number of revolutions and of the same general type, such as cross-compound condensing, it is not uncommon to receive prices of which the highest is double that of the lowest, the range being say from $10 to $20 per horse-power for an engine of 500 horse-power. For specially

designed engines requiring new patterns to be made the price may be considerably above $20. The price also varies with the condition of the market, discounts from regular prices of as much as 20 per cent being sometimes quoted in periods of dull business. The catalogues of builders usually give the weights of standard sizes of engines and a rough approximation to the probable price may be made by taking it at from 5.5 to 10 cents per pound, the lower price being for engines with heavy bed-plates and of the more simple forms.

From a number of tables and sets of curves kindly furnished by Mr. Jay M. Whitham, Consulting Engineer, Philadelphia, containing the actual bids he has received for different sizes and styles of engines, the following approximate expressions have been deduced, where P is the rated horse-power of the engine.

Type of Engine	Cost in dollars
Corliss engines:	
Single cylinder, noncondensing	$500+9P$
Single cylinder, condensing	$500+11P$
Compound, noncondensing	$1200+10P$
Compound, condensing	$1200+12P$
Compound slide-valve engine:	
Portable (locomotive) boiler, noncondensing engine and stack	$300+15P$

The cost of condensing engines is exclusive of condenser.

Professor Wickenden gives the following values for engines used to drive electric generators, these values being based on the actual costs of a large number of installations.

Type of Engine	Cost in dollars
Simple high-speed engines and settings	$350+9P$
Compound high-speed engines and settings	$1000+16P$
Simple low-speed engines and settings	$1400+11.5P$
Compound low-speed engines and settings	$2500+14.5P$

Cost of Operation. — See articles on *Power Stations* and *Depreciation*.

[Wm. Kent.]

STEAM TURBINES. — (*See also Condensers, Steam; Power Stations; Steam; Steam Engines.*) Steam turbines may be classified as impulse, reaction, and composite; single-stage and multi-stage; nozzle expansion and blade expansion; vertical and horizontal. A set of nozzles or stationary guide blades and the rotating vanes through which the steam passes immediately upon leaving the nozzles or stationary blades constitute a single "stage." If there are several sets of stationary nozzles or guide blades and rotating vanes through which the steam passes successively, the turbine is called a "multi-stage" turbine.

APPLICATIONS OF STEAM TURBINES. — The steam turbine, when designed to use steam economically, is characterized by extremely high speed of rotation. The special field of application of the steam turbine is therefore the driving of electric generators, centrifugal blowers and pumps, and other machinery in which a high speed of the motor shaft is desirable. When lower speeds are desired in the motor shaft a reduction gear of some kind is placed between it and the turbine shaft. See also articles on *Generators; Power Stations; Pumps.*

RATING OF STEAM TURBINES. — Turbine ratings are usually based on maximum sustained load. Momentary overload capacity is very large and moderate overloads of considerable duration can be carried but may require the admission of high-pressure steam to low-pressure stages by means of a secondary valve. Small turbines for driving pumps, blowers, etc., are rated in horse-power. Turbines used to drive electric generators are usually rated in connection with the generator, the combined unit or turbo-generator being rated in kilowatts. Turbo-alternators of 20,000 kilowatts capacity each are in use (1913), and still larger units are considered practicable.

DESIGN AND CONSTRUCTION OF STEAM TURBINES. — Below are noted briefly some of the chief features in the design and construction of steam turbines. For further details see the treatises by Stevens and Hobart, Moyer, Stodola, Foster, Thomas, etc.

Impulse Turbines. — An impulse steam turbine of the simplest form is a wheel similar to a water wheel, which is moved by a jet of steam impinging at high velocity on its blades. By expansion of the steam its pressure energy is converted into kinetic energy, and the wheel is propelled by the impact of the steam moving at high velocity.

De Laval Turbine. — The distinguishing features of this turbine are the diverging nozzles, in which the steam expands down to the atmospheric pressure in non-condensing, and to the vacuum pressure in condensing wheels; a single forged-steel disk carrying the blades on its periphery; a slender, flexible shaft on which the wheel is mounted and which rotates about its center of gravity; and a set of reducing gears, usually 10 to 1 reduction, to change the very high speed of the turbine to a moderate speed for driving machinery.

The number and size of nozzles vary with the size of the turbine. The nozzles are provided with valves, so that for light loads some of them may be closed, and a relatively high efficiency is obtained at light loads. The taper of the nozzles differs for condensing and noncondensing turbines. Some turbines are provided with two sets of nozzles, one for condensing and the other for non-condensing operation.

Zolley or Rateau Turbine. — The Zolley or Rateau turbines are developments of the De Laval and consist of a number of De Laval elements in series, each succeeding element utilizing the exhaust steam from the preceding. The steam is partly expanded in the first row of nozzles, strikes the first row of

buckets and leaves them with practically zero velocity. It is then further expanded through the second row of nozzles, strikes a second row of moving buckets and again leaves them with zero velocity. This process is repeated until the steam is completely expanded.

Curtis Turbine, made by the General Electric Company, is an impulse wheel of several stages. Steam is expanded in nozzles and enters a set of three or more blades, at least one of which is stationary. The blades are all non-expanding, and the pressure is practically the same on both sides of any row of blades. In smaller sizes of turbines, only one set of stationary and movable blades is used, but in large sizes there are from two to five sets, each forming a pressure stage, separated by diaphragms containing additional sets of nozzles. The smaller sizes and the more recent (1914) larger sizes have horizontal shafts. Earlier large sizes have vertical shafts supported on a step bearing supplied with oil or water under a pressure sufficient to support the whole weight of the shaft and its attached rotating disks.

Reaction and Composite Turbines.— In a simple reaction turbine steam, expanding through a set of blades or nozzles capable of rotating about a fixed axis, produces a reacting force and drives the rotating part in the opposite direction to the motion of the steam. Hero's engine is the prototype of the reaction turbine. The term "reaction" turbine, however, as ordinarily used, refers to a turbine in which the reaction principle is combined with the impulse principle, i.e., to turbines in which jets of steam striking blades or buckets inserted in the rim of a wheel give it a forward impulse, and escaping from it in a reverse direction react upon it.

Parsons Turbine. — This is a reaction turbine in which there are a large number of rows of blades, mounted on a rotor or revolving drum. Between each pair of rows there is a row of stationary blades attached to the casing, which take the place of nozzles. A set of stationary blades and the following set of moving blades constitute what is known as a stage. The steam expands and loses pressure in both sets. The speed of rotation, the peripheral speed of the blades and the velocity of the steam through the blades are very much lower than in the De Laval turbine. The rotor, or drum, on which the moving blades are carried, is usually made in three sections of different diameters, the smallest at the high-pressure end, where steam is admitted, and the largest at the exhaust end. In each section the radial length of the blades and also their width increase from one end to the other, to correspond with the increased volume of steam. The Parsons turbine is built in the United States by the Westinghouse Machine Co. and by the Allis-Chalmers Co.

The Westinghouse Double-flow Turbine. — For sizes above 5000 kw. a turbine is built in which the impulse and reaction types are combined. It has a set of non-expanding nozzles, an impulse wheel with two velocity stages (that is, two wheels with a set of stationary non-expanding blades between), one intermediate section and two low-pressure sections with Parsons blading. After steam has passed through the impulse wheel and the intermediate section, it is divided into two parts, one going to the right- and the other to the left-hand low-pressure section. There is an exhaust pipe at each end. In this turbine, the end thrust, which has to be balanced in reaction turbines of the usual type, is almost entirely avoided. Other advantages are the reduction in size and weight, due to higher permissible speed; blades and casing are not exposed to high temperatures; reduction of size of exhaust pipes and of length of shaft; avoidance of large balance pistons.

Comparison of Impulse and Reaction Turbines. — Moyer gives the following comparison of impulse and reaction turbines:

Impulse	*Reaction*
1. Few stages.	1. Many stages.
2. Expansion in nozzles.	2. No nozzles.
3. Large drop in pressure in a stage.	3. Small drop in pressure in a stage.
4. Initial steam velocities 1000 to 4000 feet per second.	4. All steam velocities low, 300 to 600 feet per second.
5. Blade velocities 400 to 1200 feet per second.	5. Blade velocities 150 to 400 feet per second.
6. Best efficiency when the blade velocity is nearly half the initial velocity of steam.	6. Best efficiency when the blade velocity is nearly equal to the highest velocity of the steam.

Experience has not made manifest any marked and consistent difference in economy and reliability between the impulse and reaction types.

Vertical Versus Horizontal Turbines. —There is also no marked difference in economy and reliability of the vertical and horizontal types. The former is more economical of floor space, especially when the base type of condenser is employed, but requires more head room, as sufficient overhead space must be allowed to permit the lifting clear, and removal of, the shaft from the casing.

Reduction Gear for Steam Turbines. — Double spiral reduction gears, usually of a ratio of 1 to 10, are used with the De Laval turbine to obtain a velocity of rotation suitable for dynamos, centrifugal pumps, etc. G. W. Melville and J. H. McAlpine have designed a similar gear, with the pinion carried in a floating frame supported at a single point between the bearings to equalize the strain on the gear teeth, for reducing the speed of large horizontal turbines to suitable speeds for marine propellers. A 6000-horse-power gear with reduction from 1500 to 300 revolutions per minute has been tested, giving an efficiency of 98.5 per cent (*Eng'g, Sept. 17; Eng. News, Oct. 21 and Dec. 30, 1909*).

TURBINES VERSUS RECIPROCATING ENGINES.* — The inherent advantages of the turbine are: (1) The perfect continuity and uniformity of effort. This permits the working parts to be made light and gives the uniform angular velocity which is desired for the parallel running of alternators. (2) The high velocity of rotation and of steam flow. This tends to great compactness, permits light weights, provides for the full expansion to high vacuum without enormous volume of expansive space, cheapens the cost of turbine and alternator, and is favorable to the efficiency of the latter. The effect of items (1) and (2) on weights, sizes and costs may be best appreciated by comparing turbine and gas-engine sets of equal maximum capacity. (3) The reduction to a minimum of condensation, radiation and leakage. (4) The absence of all lubrication from the steam space. Difficulties of lubrication with high superheat are thus obviated and the condensed steam is free from oil. (5) The maintenance of good economy over a wide range of fractional loads. (6) The great momentary overload capacity obtained from the high inertia of the rapidly rotating parts. To match this advantage in slow-speed reciprocating engines requires very heavy working parts and the addition of an expensive flywheel. The reciprocating engine can be built to equal the turbine in economy over a wide range of loads but the refinements necessary to this end are costly. For equal heat consumption the costs of large engine-alternator units are from 35 to 50 per cent greater than those of turbine sets.

Low-pressure Turbines compounded with high-pressure reciprocating engines are coming into extensive use where it is necessary to increase the capacity or improve the efficiency of existing engine plants. By combining the

* Adapted from lecture notes by Prof. W. E. Wickenden.

superior efficiency of the engine in the pressure range above the atmosphere with that of the turbine below the atmospheric range a resultant superior to the efficiency of either single type may be secured. Standard piston engines are able to sustain full-rated load when run non-condensing and often will carry from 25 to 50 per cent above rated load without danger or excessive wear. Under such conditions the water rate per kilowatt-hour is high but all the heat rejected in the exhaust is available to a low-pressure turbine; hence the net economy of the combined engine and turbine may be considerably superior to that of the engine when run condensing. By proportioning the turbine to efficiently utilize the exhaust steam and by connecting to it a high-vacuum condenser, the initial capacity of the unit may be doubled or even trebled, and if the engine is in good condition, the resultant efficiency may be superior to that obtainable from a new complete-expansion turbine of equal capacity.

Structurally, the low-pressure turbine is similar to the full-pressure type with the high-pressure stages omitted. It is, therefore, somewhat shorter but the steam spaces are necessarily greater than in a full-pressure type of equal rating. It is highly desirable that an efficient separator be installed between the engine and the turbine as the presence of moisture in the steam adds greatly to the friction against the turbine blades. When the exhaust is to be returned to the boiler it is also necessary to extract the oil from the steam as it leaves the engine.

EFFICIENCY AND LOSSES. — The maximum theoretical efficiency of a steam turbine is the efficiency of the Rankine ideal engine between the temperatures of admission and exhaust (*see Steam Engines*).

The several losses which tend to reduce the efficiency of turbines below the theoretical maximum are: (1) residual velocity, or the kinetic energy due to the velocity of the steam escaping from the turbine; (2) friction and imperfect expansion in the nozzles; (3) windage, or friction due to rotation of the wheel in steam; (4) friction of the steam traveling through the blades; (5) shocks, impacts, eddies, etc., due to imperfect shape or roughness of blades; (6) leakage around the ends of the blades or through clearance spaces; (7) shaft friction; (8) radiation. The sum of all these losses amounts to about 25 per cent of the available energy in the largest and best designs and to 50 per cent or more in small sizes or poor designs.

Condensation, leakage and radiation are of small magnitude. Windage and friction are especially marked in the high-pressure stages and the turbine is most efficient in its low-pressure stages, in direct contrast to the piston engine. The mechanical friction is relatively small, due to the small loads on wearing surfaces and the effectiveness with which they may be lubricated. Steam friction, windage and condensation are much increased by moisture in the steam. Superheated steam is particularly advantageous in turbines because of its low heat conductivity, dryness and high fluidity.

STEAM ECONOMY OF TURBINES.* — Like all heat engines the efficiency of the turbine depends on the range of expansion and the reduction of losses. Increasing the expansion range by raising the admission pressure affords a relatively small gain in efficiency. The chief advantage resulting from high initial pressure is in the decreased size of the turbine of a given capacity. The relation of initial pressure to the steam and heat consumption per unit of output varies somewhat with the individual turbine, but the general relation with fixed conditions of vacuum and superheat is shown in Fig. 1.

The advantage gained by increasing the range of expansion at the lower end greatly exceeds that gained by an equal pressure increment at the upper end of

* Adapted from the lecture notes of Prof. W. E. Wickenden.

the cycle. In the utilization of high vacua the turbine greatly surpasses the engine. Fig. 1 shows the relation of vacuum to turbine efficiency for typical units. This relation depends to a marked degree on the design of the particular turbine and is therefore not identical in all units of a given general type.

Effect of Vacuum on Economy. — The economical limit of vacuum in turbines is much higher than in engines. The attainment of very high vacua involves a very heavy investment in condensers and auxiliaries and a considerable consumption of heat for their operation. The ultimate effect on plant economy is therefore decidedly less than the percentage gain indicated in Fig. 1. Factors unfavorable to high vacuum are a poor load factor for the unit; costly, warm or corrosive cooling water; the necessity of artificially cooling condensing water when the supply is limited; and very cheap fuel.

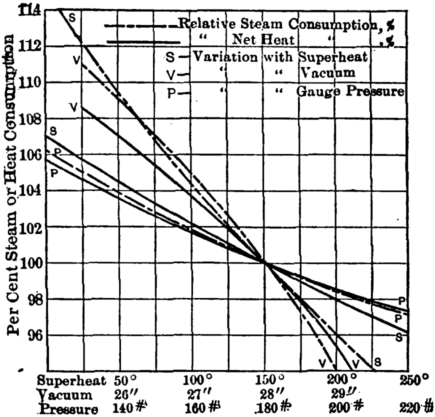

Fig. 1. Relations of Turbine Efficiency to Steam Conditions and Vacuum

The question of the most economical vacuum must be determined by carefully weighing against each other the annual charges on the condenser system, interest, depreciation, attendance, repairs, and the net cost of water for its operation included, and, on the other hand, the annual saving in total fuel consumed plus the saving on boiler-plant fixed charges and operation. Such

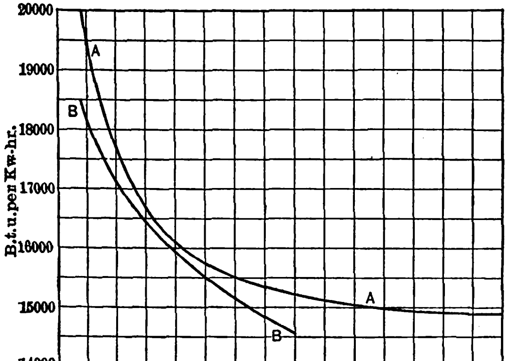

Fig. 2. Average Full-load Net Heat Consumption of Turbines

A. American types, mean values from guarantees and tests
B. Results of 50 European Tests

an analysis takes due account of the heat consumed in driving the auxiliaries. Where an abundant supply of cold condensing water is available, experience indicates that the highest vacuum attainable is a good investment in connection with large units operated at load factors of 60 per cent, or above. With ordinary central-station conditions vacua of from 27 to 28 inches are most advantageous.

Effect of Superheat on Economy. — Superheat of almost any practicable degree improves turbine efficiency, though the net saving is much less than that indicated by the water rate, due to the extra heat content of superheated steam of high temperature. On account of the influence of superheat on the first cost and maintenance expense of piping, valves and fittings, also because of the difficulties in providing for expansion of turbine parts at very high temperatures, the tendency of American practice is to exceed a steam temperature of 500° F. only in very large units, though the tendency in Europe is toward a higher limit. Fig. 1 shows the effect of superheat on steam consumption and net heat consumption of steam turbines, the relation being practically uniform for all types.

Effect of Size and Type on Economy. — The efficiency of the turbine, like that of the engine, improves as the size of the unit increases, see Fig. 2. Large units are relatively cheaper than small, and afford better economy in piping, condensing equipment, space, attendance and maintenance.

A turbo-generator is rated as a single unit. The momentary and sustained overload capacity of the turbine proper is very large, but the generator is much restricted by its ability to dissipate the heat developed in its parts. The usual ratings are based either upon maximum sustained capacity (*M* in Fig. 3) or upon normal sustained capacity with an allowable overload of 25 per cent for a two-hour period (*N* in Fig. 3).

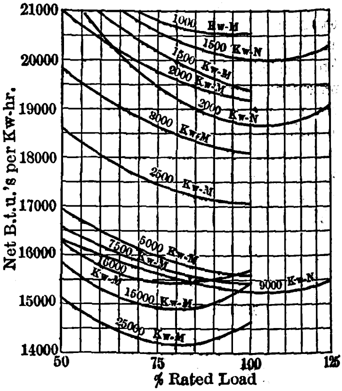

Fig. 3. Net Heat Consumption of Modern Turbines

M. Maximum Rating. N. "Normal" Rating

Experience has not made manifest any marked or consistent differences in economy and reliability between the several commercial types. The vertical type is not well suited to the highest speeds, but is especially economical of floor space in connection with the base type of condenser. It requires greater head-room than the horizontal type. Fig. 4 shows the steam consumption of a number of small non-condensing turbines (*see paper by G. A. Orrok, Trans. A.S.M.E., 1909*). All curves are test results.

ECONOMY OF COMBINED TURBINE AND ENGINE UNIT. — The following is reported by H. G. Stott and R. J. S. Pigott in *Jour. A.S.M.E.*, Mar., 1910. The steam engine is one of the 7500-kilowatt Manhattan type engines at the 59th St. Station of the Rapid Transit Co., New York, with two 42-inch horizontal high pressure and two 86-inch vertical low pressure cylinders, and the turbine, also 7500 kilowatt, is of the vertical three-stage impulse type. The principal results are summarized as follows: An increase of 100 per cent in the maximum capacity and 146 per cent in the economical capacity of the plant; a saving of about 85 per cent of the condensed steam for return to the

boilers [it was previously wasted]; an average improvement in economy of 13 per cent over the best high-pressure turbine results, and of 2.5 per cent (between

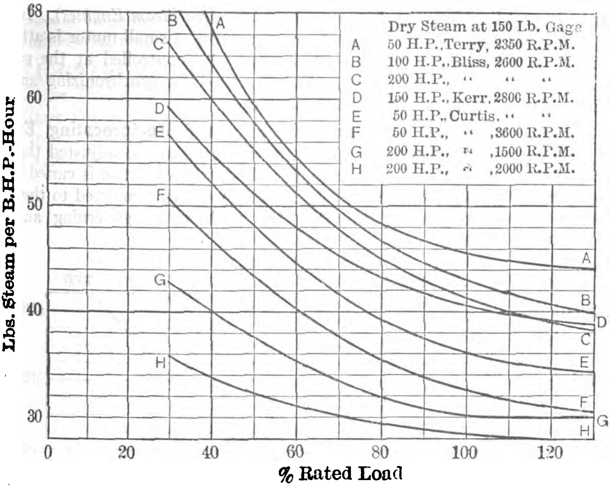

Fig. 4. Steam Consumption of Small Non-condensing Steam Turbines

7500 and 15,000 kilowatts) over the results obtained by the engine alone; an average thermal efficiency between 6500 and 15,500 kilowatts of 20.6 per cent. [This efficiency is not quite equal to that reached by triple-expansion pumping engines.]

TESTING OF STEAM TURBINES. — Turbines are tested in the same way as reciprocating steam engines, measuring the power by a Prony brake or by an electric generator whose efficiency at different loads is known, and the steam consumption by weighing the water discharged from the condenser.

SPECIFICATIONS. — See *Specifications* in article on *Steam Engines.*

OPERATION.* — Several important features are noted below. For additional information see article on *Power Stations.*

Oil-pressure System for Step Bearing of Vertical Turbine. — When running the end of the shaft is lifted slightly from its seat and supported by a forced circulation of water or oil under a pressure of from 500 to 1200 pounds per square inch. This pressure is produced by a special step-bearing pump which may be of the steam-driven, direct-acting type or of the motor-driven, triplex type, and is reinforced by a heavily weighted plunger accumulator. When a double pump equipment is installed the second may serve as a reserve and, if of the motor-driven type, may readily be arranged to automatically take up the load if the accumulator falls to a certain point, due to the failure or inadequacy of the primary pump. The horizontal-shaft type is subject to an end thrust, which must be neutralized by dividing the turbine into two sections through which the steam flows in opposite directions or by the use of pressure rings opposed to the thrust on the turbine.

* Adapted from lecture notes by Prof. W. E. Wickenden.

Speed Control. — Turbines having nozzle expansion are most efficiently governed by varying the number of active nozzles. Reaction turbines are governed by the intermittent throttling of steam at the admission valve. The governor is usually of the shaft or flywheel type (*see Steam Engines*). In both types, when used for driving alternators in parallel, a small motor is attached to the governor spring so that the tension may be controlled at the switchboard. This affords a convenient control of speed for synchronizing and adjusting the loads taken by the several machines.

Speed Control of Combined Turbine and Reciprocating Engine Unit. — In central-station service the two elements are so adjusted that the turbine takes all the steam from the engine, the load on the two is varied simultaneously and the two are electrically coupled by being connected to the same bus bars. This arrangement simplifies the problem of governing and the

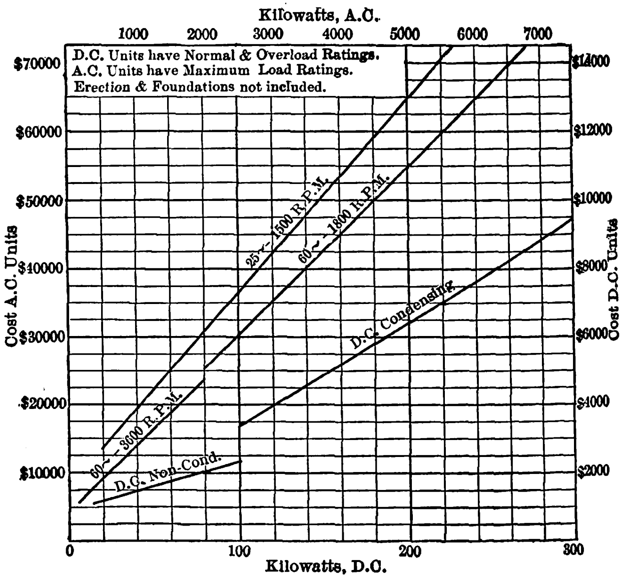

Fig. 5. Approximate Cost of Turbo-generator Sets

division of load. It has not been found advantageous to place a governor on the turbine under such conditions. The turbine operates under variable admission pressure, depending on the load. The turbine should be equipped with a speed-limiting relay, which opens the atmospheric exhaust from the engine should the speed of the turbine become unsafe.

COST OF STEAM TURBINES. — Small turbines for driving pumps, blowers, etc., cost from $20 to $40 per horse-power.

In Fig. 5 are given the total costs of various turbo-generator sets in 1912. These costs include both the turbine and generator but do not include condensers and auxiliaries. The curves were kindly supplied by Prof. W. E. Wickenden and represent the average of the actual costs of a number of units of various

capacities. Impulse and reaction turbines cost approximately the same. Turbine costs are subject to considerable variation, the tendency being a decided decrease in the cost per kilowatt from year to year. The costs given in the curves should therefore be checked against actual quotations, even when used in preliminary estimates.

[WM. KENT.]

STEEL. — (*See also Iron, Pig and Cast; Castings, Iron and Steel; Rails, Track and Third.*) Carbon steel (the ordinary commercial steel) may be defined as an alloy of iron and carbon produced by any one of the methods described in the following article. It differs from wrought iron in not being slag bearing and from cast iron in being malleable at certain temperatures.

Slag is the substance which collects on the surface of molten iron or steel in the blast furnace, converter or open-hearth furnace. Its constitution varies with the process but it includes oxides of the various impurities found in the iron such as silicon, aluminum, phosphorus, calcium and magnesium. It may also include some oxide of iron. The slag from blast furnaces is often very rich in calcium owing to the amount of limestone added to the charge as a flux. The manufacture of Portland cement from blast-furnace slag is an important industry. The process of puddling used in making wrought iron involves the mixing of some of the slag with the iron, thus making it an integral part of the finished product as explained in the article on *Iron, Wrought.*

METALLURGY. — The various processes by which steel is at present manufactured are described in the following paragraphs:

Bessemer Process. — This process consists of the burning out of most of the impurities and carbon contained in molten iron by the aid of a blast of unheated air, and subsequent recarburization of the mass by the addition of spiegel-eisen or ferro-manganese. The molten material is placed in a pear-shaped vessel called a converter and the blast is introduced through openings in the bottom. After the process has continued long enough to convert the iron into steel, the molten material is either poured into iron molds forming ingots which are later rolled or hammered into commercial shapes, or else cast into *steel castings.*

Two processes are in use, the acid and the basic; in the former the converter lining is of refractory acid materials composed principally of silica, so that the phosphorus and sulphur in the charge are unreduced; in the latter, the converter is lined with burnt dolomite, and lime is added to the charge to reduce the phosphorus and sulphur. The heat necessary for the process is obtained from the combustion of silicon in the acid process and of phosphorus in the basic process. The acid process alone is in use in the United States owing to the prevalence of low phosphorus and sulphur ores. Steel of fair quality is produced by this process at low cost and with great rapidity, but Bessemer steel is gradually being replaced for important structures by the more reliable open-hearth steel.

Open-hearth Process. — This process consists of the reduction of the carbon and other impurities contained in a mixture of pig iron, scrap iron or scrap steel, and iron ore by exposure for seven or eight hours to an intense heat obtained from a mixture of producer gas and air, the process being stopped when the bath is found to have the right proportions as determined by physical and chemical analyses. The steel is then withdrawn from the furnace and either poured into ingots or cast into usable forms. Steel of excellent quality for structural purposes is thus produced in large quantities, a single furnace often having a capacity of 50 tons.

Duplex Process. — This process consists of a combination of the Bessemer and open hearth; pig iron is first blown into the converter to remove the silicon and a portion of the carbon; it is then transferred to the open hearth, where it is dephosphorized and the carbon reduced to the proper percentage. The process permits the use of a poorer grade of material than the Bessemer, and gives a higher grade of finished product, while the speed of production is superior to that of the open hearth.

Crucible Process. — This process consists of melting down, in covered clay or graphite crucibles, wrought iron (sometimes diluted with steel scraps) with charcoal, ferro-manganese and various so-called physics, such as salt, oxide of manganese, etc. The crucibles hold from 50 to 100 lb. each. Crucible steel is high in carbon and low in sulphur and phosphorus. It is superior to Bessemer and open-hearth steel and is used for tool making.

Cementation Process. — This process consists of converting wrought iron into steel by piling iron bars and charcoal together, bringing to a yellow heat and keeping in this condition for a period extending from ten days to two weeks. The steel thus obtained is known as blister steel. If the blister steel is cut, piled, heated and forged, *shear* steel is produced; if the operation is repeated on shear steel, *double shear* steel is obtained. Blister steel is frequently melted in the crucible to free from slag; the resulting product is of the highest quality and is used in making the finest grades of cutting tools, such as razors. Case hardening is a special form of cementation by which the outer surfaces of articles forged from wrought iron or steel are hardened. Harveyizing of armor plate is also a cementation process.

MECHANICAL TREATMENT. — (*See also Steel Mills, Electric Drive of.*) Steel made by any of the preceding processes may be put into usable form either by casting, or by forging while hot under the hammer, or usually by rolling while hot between heavy grooved rollers, the latter process being used for rods, plates, rails, and structural shapes such as angles, channels and I-beams. The rolling process is usually divided into two parts: (*a*) the reduction of the ingot into *blooms* or *billets* by the *blooming mill;* and (*b*) the reduction of the blooms or billets into commercial shapes by the *shaping mill.*

The blooming mill consists of a pair of horizontal grooved rollers, one above the other, between which the ingot is passed back and forth, the rolls being gradually forced closer together. These rolls are actuated by a reversing engine. This process reduces the ingot from a block of steel perhaps 16 inches square by 6 feet in length to a bar of small cross-section, usually rectangular and of considerable length. This is then cut into sections several feet in length which are called blooms if the cross-section contains more than 36 square inches and billets if less. In England this mill is called a cogging mill.

The shaping mill is similar to the blooming mill, but there are usually three non-reversing rolls in a vertical plane, the bloom passing forward between the lower and middle rolls, and returning between the middle and upper roll.

HEAT TREATMENT; CRITICAL TEMPERATURE. — When iron or steel cools from a high temperature, say 1000° C., the rate of cooling is not uniform, but is marked by certain periods of retardation accompanied by spontaneous evolution of heat, the opposite phenomena occurring when the temperature is increased. There are in general three of these critical points which are designated by metallurgists by the letters A_1, A_2 and A_3, A_1 being at the lowest temperature. Owing to *lag* the changes occur at slightly lower temperatures on cooling than on heating, and to distinguish between them, the cooling points are designated Ar_1, Ar_2 and Ar_3, and the heating points Ac_1, Ac_2 and Ac_3. These points vary with the percentage of carbon, and for certain grades of steel the three cooling points may be merged into one and also the three heating points. With favorable conditions when the temperature Ar_1 is reached an increase in temperature of the metal may be detected by its change of color. This point is called the point of recalescence. At this temperature also a softening of the metal occurs. An interesting feature of the point A_2 is that at a higher temperature steel is *non-magnetic,* but in passing through Ar_2 it becomes suddenly *magnetic.* *See Magnetic Properties of Iron and Other Metals.*

The approximate values of these critical points in degrees Centigrade as given by Sauveur are shown in the following table:

CRITICAL TEMPERATURES IN DEGREES CENTIGRADE

Grade of steel	Low carbon	Medium-high carbon	High carbon
Carbon content, per cent	0.1	0.45	Above 0.85
Ar_1	675	650 to 700	675
Ar_2	750	725	675
Ar_3	850	725	675
Ac_1	700	...	...
Ac_2	750	...	...
Ac_3	875	...	...

ANNEALING. — Steel with a coarse structure due to rapid cooling may be improved in grain by heating to a temperature varying with the carbon content and cooling slowly. The accompanying table gives the annealing temperatures which are commonly specified for this purpose.

Range of carbon content, per cent	Range of annealing temperature	
	° C.	° F.
Less than 0.12	875 to 925	1607 to 1697
0.12 to 0.29	840 to 870	1544 to 1598
0.30 to 0.49	815 to 840	1499 to 1544
0.50 to 1.00	790 to 815	1454 to 1499

The object should be kept at the annealing temperature long enough to insure a uniform temperature throughout and then cooled. The higher the carbon, or the greater the ductility and softness required, the slower should be the cooling. It is usually sufficient to remove the object from the furnace and to allow it to cool in air protected from rain, snow and drafts. Steel containing more than 0.50 per cent carbon should cool more slowly until the color dies out before removing from the furnace; it may then be removed and cooled in air. To remove the effects of cold working the object should be heated to about 775° C. and cooled with a slowness depending upon the thickness.

For detailed specifications see *Year Book of Amer. Soc. for Test. Mat.*

CARBON STEEL. — The alloy of carbon and iron of which ordinary carbon steel is composed is divided into the five following groups by Sauveur:

Grade of steel	Hardness	Carbon content, per cent
Very low carbon	Very soft	Not over 0.10
Low carbon	Soft	Not over 0.25
Medium-high carbon	Half hard	0.26 to 0.60
High carbon	Hard	Over 0.60
Very high carbon	Hard, extra hard	Over 1.25

The properties of these different groups when made under normal conditions depend upon the relative amounts of the following constituents:

Ferrite, or iron free from carbon, this being the same as the ferrite in wrought iron (q.v.).

Pearlite, consisting of a mixture of iron carbide and ferrite.

Cementite, or iron carbide, with the formula Fe_3C, combined with a varying amount of carbide of manganese.

Austenite and Martensite. — Steel that is suddenly cooled from a high temperature contains also certain other compounds of iron and carbon, the two of most importance being known as *austenite* and *martensite.* The former is generally considered as a solid solution of carbon, or of the carbide Fe_3C, in iron in the allotropic condition in which the latter exists at a high temperature (above 875° C.). It is not a constituent of constant composition, and is seldom found in ordinary steels since it is rapidly transformed in cooling into an aggregate of ferrite and cementite. To obtain it highly carburized steel may be suddenly cooled from a temperature of 1000° C. or more by a bath such as ice cold water. It may also be obtained by slow cooling if the steel contains a considerable portion of manganese or nickel. Martensite is generally believed to be an early stage in the transformation of austenite.

Phosphorus and Sulphur. — The common injurious impurities in carbon steel are phosphorus and sulphur, both of which cause brittleness and should be allowed only in small quantities. Specifications (*see section below on this topic*) frequently forbid more than 0.05 per cent of sulphur and 0.04 per cent of phosphorus. Other impurities commonly occuring in small quantities in steel are silicon and manganese, which in small quantities help to reduce blow holes by their deoxidizing action. These elements while often present in higher percentages than the carbon have comparatively little influence upon the strength of ordinary carbon steel.

Composition of Low-carbon Steel. — Low-carbon steel consists chiefly of a mass of ferrite with pearlite occuring at the junction of the grains of ferrite, the percentage of the former decreasing in medium and hard steels until in steel having 0.8 per cent to 0.9 per cent carbon, it disappears entirely, the steel then consisting exclusively of pearlite. In still higher carbon steels some of the pearlite is replaced by free cementite, the substance which gives steel its hardening property.

Strength and Weight of Carbon Steel. — The tensile strength of steel varies with its composition. For ordinary carbon structural steel the working values given in the following table may be adopted with safety:

Nature of stress	Working strength, pounds per square inch
Tension on net section, and extreme fiber stress in bending	16,000
Compression in columns*	$16{,}000 - \frac{70\,l}{r}$, with a maximum of 14,000
Shear on net section of plate-girder webs and on machine-driven shop rivets	12,000
Bending on extreme fiber of pins	24,000
Bearing on pins and shop-driven rivets	24,000
Bearing on hand-driven rivets	18,000
Shear on hand-driven rivets	9,000
Modulus of elasticity	28,000,000 lb. per sq. in.

* In the expression for compression in columns, $\frac{l}{r}$ = maximum value of ratio of the unsupported length of column to radius of gyration, both values being expressed in inches. This ratio should be restricted by the form of the column so that it will not exceed 100 for main members and 120 for lateral and other secondary members.

Steel weighs approximately 490 lb. per cu. ft., or 2 per cent more than wrought iron.

Specifications for Structural Steel and Steel Castings.—The American Society for Testing Materials has adopted standard specifications for steel to be used in various classes of structures. (*See A.S.T.M. Yearbook.*) Among the items covered are the chemical and physical properties of the material, the specimens and methods of tensile and bend tests and the permissible variation in weight and gauge. The following tables give the requirements as to chemical composition and tensile properties as given in the Society's specifications for structural steel for bridges and ordinary steel castings as adopted Aug. 25, 1913.

CHEMICAL COMPOSITION

Elements considered	Structural steel	Rivet steel	Steel castings
Phosphorus, max., per cent;			
Acid	0.06	0.04	0.06
Basic	0.04	0.04	0.06
Sulphur, max., per cent	0.05	0.04	0.05

TENSILE PROPERTIES

Properties considered	Structural steel	Rivet steel	Steel castings
Tensile strength, lb. per sq. in.	55,000 to 65,000	48,000 to 58,000	60,000 minimum
Elongation in 8 in., min., per cent	$\frac{1{,}500{,}000}{\text{Tensile strength}}$	$\frac{1{,}500{,}000}{\text{Tensile strength}}$	....
Elongation in 2 in., min., per cent	22	....	20

SPECIAL OR ALLOY STEELS. — The more usual forms of special steels and their uses, composition and general characteristics are as follows:

Nickel Steel. — Steel containing a considerable percentage of nickel, but generally not more than $3\frac{1}{2}$ per cent, is called nickel steel. This steel has a greater strength and a higher elastic limit than carbon steel, and practically the same modulus of elasticity; it is more ductile in proportion to its strength and somewhat harder than carbon steel of like properties, it is more expensive because of the cost of the nickel, and the additional cost of working. Nickel steel has been used considerably in recent years for bridges of large size, for steamer shafts, automobile parts, etc.

Invar Steel. — This is a nickel steel containing about 36 per cent of nickel. Its coefficient of expansion is practically zero. It is used in making steel tapes for base line measurements in geodetic surveying.

Manganese Steel. — The steel commonly known as manganese steel contains from 12 per cent to 13 per cent of manganese and generally from 1.25 per cent to 2.00 per cent of carbon for castings; for forgings or rolled steel, less carbon is used. It is austenitic in composition and is very hard without brittleness, making it well fitted for railroad frogs, railroad rails or curves and burglar-proof safes. It is adapted principally to parts that can be cast, since working it with tools is practically impossible and forging is difficult. It is not used for structural work as its elastic limit is so low as to offset the advantage of its great strength. Like nickel, the manganese interferes with the transformation of austenite to pearlite during cooling. It is often called "Hadfield" steel from the name of its inventor.

Chrome Steels. — Steels containing from 1 per cent to 2 per cent of chromium are very hard and have a high elastic limit. They are well adapted for armor-piercing projectiles, steel balls, files and automobile gears. Krupp armor plate is said to contain 3.25 per cent nickel, 1.5 per cent chromium and 0.25 per cent carbon.

Vanadium Steels. — The addition to steel of a small amount of vanadium, usually less than 0.3 per cent, adds greatly to the elastic limit, ductility and resilience. Vanadium is especially advantageous in increasing strength, toughness and temper of nickel and chromium steels. This steel is particularly useful for springs, axles and automobile parts.

Silicon Steels. — The only silicon steels in use contain less than 5 per cent of silicon. The alloy recommended by Hadfield, its patentor, contains 2.75 per cent silicon with the smallest possible amounts of carbon, manganese and other impurities. Such steel has a greater magnetic permeability than the purest iron, and also a high electrical resistance. Its magnetic hysteresis is low. It is a valuable material for use in electromagnetic and in electrical generating machinery. See *Magnetic Properties of Iron.*

Tungsten Steels. — These steels have the property of becoming martensitic upon heating to a high temperature and air cooling and are said to be "self-hardening." Such steels are used for springs, magnets and with manganese added for self-hardening tools. See also *High-speed Steels and Magnetic Steels, below.*

Self-hardening Steels. — Steel which is hard without tempering and cannot be annealed by known processes is called self-hardening steel. All such steels are non-magnetic. Any steel which is in an austenitic condition at atmospheric temperature is self-hardening. (*See Mushet Steel, below.*)

Ternary and Quartenary Steels. — These are steels consisting of three or four essential components, viz., iron, carbon and one or two alloys. Some of the more important ternary steels are nickel steel, manganese steel, chrome

steel, tungsten steel and silicon steel. Among quartenary steels are nickel-chromium, nickel-manganese, nickel-vanadium, tungsten-chromium, etc. The effect of these various alloys upon carbon steels is very striking and their possibilities are very great.

Chrome-nickel Steel. — The chrome-nickel steels in use are pearlitic and contain moderate amounts of carbon, nickel and chromium. Such steel has a high elastic limit combined with high ductility and has greater hardness, resilience and wearing power than carbon steels. It is used in automobile construction and for the manufacture of armor plate.

Chrome-tungsten Steel. — Tungsten and chromium have the property of producing a finely martensitic structure in steel when heated to a high temperature and cooled in air. The martensite in this case is so stable that the steel may be heated to a red heat without losing hardness. Such steels are known as "high speed steels" (q.v.).

High-speed Steels. — These steels have a finely martensitic structure which is stable up to red heat. They may contain from 0.25 per cent to 1.00 per cent of carbon, from 5 per cent to 25 per cent tungsten, 2 per cent to 10 per cent of chromium and seldom over 0.40 per cent of manganese. Tungsten may be replaced wholly or in part by molybdenum. Steels of this character are of great importance in machine work as tools made from them can be driven without injury until the cutting edge is red hot.

Mushet Steel. — This steel contains both tungsten and manganese. It is a self-hardening steel and has been used for many years for tools which make very heavy or deep cuts such as is required for armor plates. The speed allowable is a little greater than for carbon steel, but it lasts a long time without grinding.

Magnetic Steels. — Steels containing 4 per cent to 5 per cent of tungsten and from 0.5 per cent to 0.7 per cent of carbon if heated to red heat and quenched in water will retain their magnetism better than carbon steel. The addition of chromium increases the permanency but decreases the magnetic force.

PRICE OF STRUCTURAL STEEL, F.O.B. PITTSBURGH. — The following prices show market quotations in April, 1913 (*from Iron Age, April 10, 1913*). I-beams, 3 to 15 in.; channels 3 to 15 in.; angles 3 to 6 in. on one or both legs ¼ in. thick and over; and zees, 3 in. and over, 1.45 to 1.70 cents per lb.; *extras* on other shapes and sizes are as follows:

I-beams over 15 in.	0.10	cents per lb.
H-beams over 18 in.	0.10	” ” ”
Angles over 6 in. on one or both legs	0.10	” ” ”
Angles, 3 in. on one or both legs, less than ¼ in. as per steel bar card, Sept. 1, 1909	0.70	” ” ”
Tees, structural sizes (except elevator, hand rail, car truck and conductor rail)	0.05	” ” ”
Angles, channels and tees, under 3 in. wide as per steel bar card, Sept. 1, 1909	0.20 to 0.80	” ” ”
Deck beams and bulb angles	0.30	” ” ”
Hand rail tees	0.75	” ” ”
Cutting to lengths, under 3 ft. to 2 ft. inclusive	0.25	” ” ”
Cutting to lengths, under 2 ft. to 1 ft. inclusive	0.50	” ” ”
Cutting to lengths under 1 ft.	1.55	” ” ”

No charge for cutting to lengths 3 ft. and over.

FREIGHT RATES ON FINISHED IRON AND STEEL PRODUCTS. — (*From Iron Age, April 11, 1913.*) Freight rates in April, 1913, from Pitts-

burgh in carloads, per 100 lb. were: New York, 16 cents; Philadelphia, 15 cents; Boston, 18 cents; Buffalo, 11 cents; Cleveland, 10 cents; Cincinnati, 15 cents; Indianapolis, 17 cents; Chicago, 18 cents; St. Louis, 22½ cents; Kansas City, 42½ cents; Omaha, 42½ cents; St. Paul, 32 cents; Denver, 84½ cents; New Orleans, 30 cents; Birmingham, Ala., 45 cents; Pacific coast, 80 cents on plates, structural shapes and sheets No. 11 and heavier; 85 cents on sheets Nos. 12 to 16; 95 cents on sheets No 16 and lighter; 65 cents on wrought pipe and boiler tubes.

STEEL MILLS, ELECTRIC DRIVE OF.—(*See also Flywheels for Load Equalization; Motors, Industrial Applications of.*) The application of electric motors to steel mill service may be divided in two general classes; 1. that dealing with the application of motor drive to the main rolls, that is to those rolls in which the ingot or billet is reduced in section, and 2. that dealing with the problems of electrifying the numerous other auxiliary machines and devices, such as tables, screw-downs, charging machines, etc.

MAIN-ROLL APPLICATION.—The term "mill" is sometimes used to designate a single stand or group of stands, and sometimes to include the main rolls and all auxiliaries involved in the production of a given class of materials. The stands are generally classified according to the arrangement of rolls and method of operation, that is two-high or three-high, the two-high being either reversing or non-reversing, see Fig. 1.

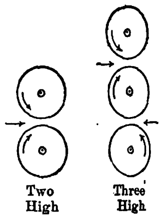

Fig. 1. Diagram of Two-high and Three-high Rolls

Reversing and Non-reversing Mills.—The great majority of rolling mills in this country are of the non-reversing type where the rolls run continuously in one direction. Flywheels are used to equalize the input to the motor. The ideal combination would be to use a motor of sufficient capacity to carry the average load and a flywheel which would take care of all the peaks. Such a wheel would be too large and a compromise between the motor and flywheel must generally be made. As opposed to the heavy flywheel effect required by the two-high or three-high non-reversing mill, the minimum flywheel effect consistent with the necessary speed and torque is desirable for reversing mills. In order to avoid the reflection of peak loads of these motors back upon the system, it is customary to interpose a flywheel motor-generator set with one or more generators between the power station and the mill. In order to minimize the flywheel effect of the reversing motor, two or more direct-current motors are often mounted on the same shaft and their armatures connected in series. This arrangement renders possible the use of smaller armature diameters with consequent reduction of acceleration losses and also permits the use of a high-voltage generator on the flywheel set. The mill motor is separately excited and perfect speed control is obtained by varying the excitation of the generator on the flywheel set. Direct-current generators can be designed for 2400 volts to give excellent results when operating two 1200-volt motors in series.

Power Required.—Rolling mill loads are irregular in the extreme due to the intermittent character of the process. For any particular ingot the motor load consists of periods of heavy duty increasing in length with the length of the metal in the pass, interspersed with periods of friction load only. With a given mill the load varies widely with the difference in the section rolled, differences in temperatures of metal, personal equation of the operator, etc. The practical determination of the power required to roll steel is a matter of elaborate and extensive tests under widely varying conditions. For methods and results see papers in *Bibliography*. The information for predetermining the sizes of motor and flywheel for an installation must cover the following points:

Type of mill; rail, plate, etc.	Time between passes.
Diameter and speed of rolls.	Elongation in each pass and total.
Weight of ingot.	Initial length.
Initial and final section.	Average and maximum rate of rolling.
Number of passes.	Temperature of metal.

Load Curves.—From these data and a thorough understanding of the many variable factors encountered in steel-mill practice, it is possible to lay out load curves similar to the ones shown in Figs. 2, 3 and 4. From such curves it is then possible to determine the proper size of the motor and the flywheel.

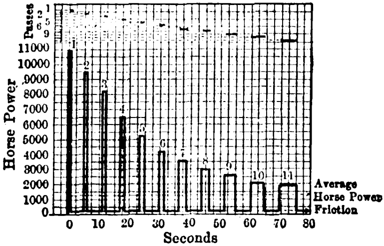

Fig. 2.

The typical curve shown in Fig. 2 represents a load curve calculated for a two-high single-stand reversing blooming mill in which a 3000-pound ingot is reduced from initial to final section in eleven consecutive passes occurring at 5-second intervals. This curve is characteristic of blooming mills, roughing mills, etc., which in general give the lowest load factor. The work done in horse-power seconds is indicated by the area under the curve. Fig. 3 is representative of a large and mixed class with medium load factor, such as small merchant mills, bar mills, sheet mills, etc. Fig. 4 shows a load factor so high as to be scarcely approximated except in merchant mills with a large number of stands working at full capacity.

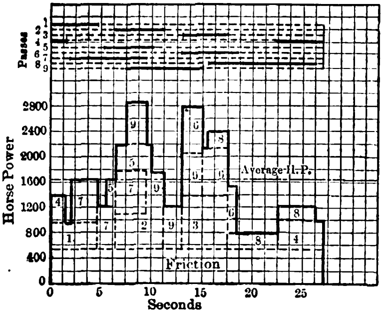

Fig. 3.

In determining the most suitable size of motor for the work indicated by the load curve full consideration must be given to the fact that excessive loads may be encountered at times due to the low temperatures of the metal in the pass, too heavy draft or other causes, and ample margin allowed. Assuming for the moment that by properly combining simultaneous passes on the several stands and the application of a suitable flywheel the load curve has been flattened out as much as appears possible, the question of continuity of service and duration of peaks must be considered to determine whether the limiting feature will be maximum torque or heating. With rolling-mill motors the limiting feature of design is usually torque rather than heating. The motor rating is determined by a consideration of the root-mean-square value of the current for a single cycle, and the frequency and duration of successive cycles.

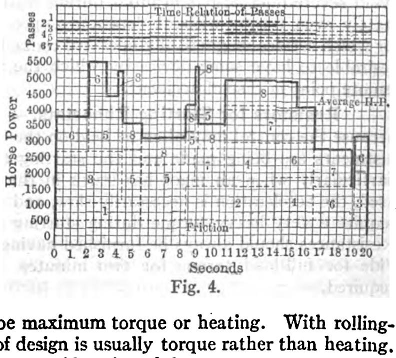

Fig. 4.

Use of Induction Motors. — The choice of alternating- or direct-current motors for main rolls must be determined by a careful consideration of several factors, chief of which are the capacity of individual units, constant, variable or adjustable speeds, reversing or non-reversing, transmission distance, existing power-station equipment, etc.

It is in general conceded that for large units and constant speed, constant-load service induction motors with phase-wound rotors possess many advantages over direct-current motors. This is due to the ruggedness of construction and simplicity of operation of the induction motor, and to the facility with which alternating current may be stepped up to any desired voltage, thus rendering the problem of economic power distribution relatively simple.

For the comparatively few main roll drives where it is essential that close regulation be maintained for a large number of speeds, each constant under varying loads, a direct-current motor with shunt characteristics has until recently been practically necessary. It is now possible to obtain these characteristics by using standard induction motors with phase-wound rotors and speed-regulating sets. The method of avoiding the dissipation of energy as heat in the control rheostat consists in replacing the non-inductive external resistance by a compensated commutator motor which may be mounted either on the shaft with the main motor, or more commonly as one element of a two-unit motor-generator set. In the latter case the second element is a squirrel-cage induction motor, driven slightly above synchronism by the commutator motor and operating as an induction generator, thus returning to the line energy proportional to the slip of the main motor less the losses in the regulating set itself.

Control Equipment for Induction Motors. — The control for large steel mill motors is important because of the size of the apparatus involved and the extreme importance of continuous operation. Most motors for main-roll drive are started up at the beginning of a shift, immediately brought up to full speed, and left running until the end of the shift. Provision must be made for running a short time at reduced speed when desired, for making adjustments to the mill, and for reversing, in order to back out ingots which have stuck in the mill. If a flywheel is used, there should also be provision for quick stopping, so that if a spindle is broken, the motor can be brought to rest quickly and a new spindle substituted without delay. Current-limiting relays are desirable in order to avoid severe fluctuations in input during starting and to maintain an approximately even torque without depending upon the intelligence of the operator, for which service magnetically-operated contactors are necessary. It is always desirable to have some device by which the motor can be shut down from a remote point in case of accident.

Resistors for Starting Rheostats. — The resistance should be liberal, because the control may often be held on the first point for some time when adjustments are being made and the starting torque may sometimes be heavy, particularly when an ingot has stuck in the rolls. Also, where a flywheel is used, the acceleration is necessarily slow, and some mills, particularly cold rolls, require a very heavy torque during starting and until they have warmed up. Resistances should always be furnished having at least enough capacity to provide for full-load torque for two minutes. In special cases more will be required.

Contactors and Oil Switches. — Where 440- or 550-volt alternating current is used, contactors can be employed for both primary and secondary, and remote control is an easy matter. 2200- or 6600-volt motors require oil switches in the primary, which cannot be operated readily by means of alternating current. They can be operated with direct-current, but this complicates the system and makes the operation of the alternating-current motor dependent

upon the direct-current supply. As remote control is not essential in the large majority of cases, hand-operated oil switches can be used.

Simple-control System. — Fig. 5 shows a typical diagram of connections for a simple-control system. The incoming line passes through discon-

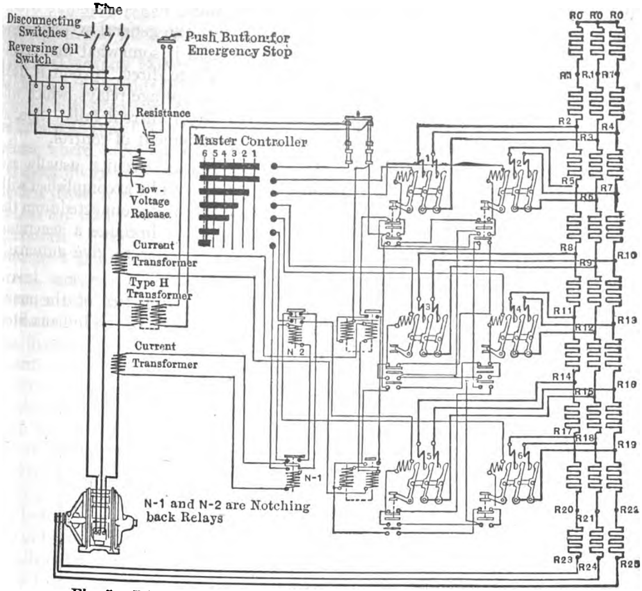

Fig. 5. Diagram of Mill-control System with Induction Motor

necting switches by means of which the motor and all the control equipment can be cut off when repairs or adjustments are to be made. The hand-operated oil switch is made double-throw to provide for forward and reverse operation. A push button or control switch located in the mill can be used to trip the switch by short-circuiting the no-voltage release for emergency stopping. The slip rings are connected permanently to a three-phase resistance. Contactors (double-pole, where sizes permit) are used for short-circuiting successive portions of the resistance as the motor accelerates. The operating current for the contactors passes through a master controller so that the motor can be held with all resistance in circuit or on any one of several intermediate points between that and complete short-circuit. Current-limit relays in series with the primary line govern the rate at which the contactors close.

No-voltage release is obtained automatically on the secondary contactors, because they are operated by current received from the primary line. If the primary oil switch is opened for any cause, the operating current for the contactors is interrupted, so that they open. The acceleration is always governed by the current-limit relays independent of the position of the master controller. For ordinary starting and for stopping the master controller can be left on the full running position and the oil switch simply closed and opened.

It is standard practice to use 50 per cent more ohms in the secondary resistance than the value required to give full-load torque at standstill. This value limits

the current on reversal at full speed to 133 per cent of full-load current, so that full-speed reversal for quick stopping causes no more shocks on the motor or line than will be experienced in ordinary operation. If a flywheel is used, a small amount of resistance (sufficient to give 5 or 10 per cent slip at full load) is left permanently connected in the secondary.

Where motors having two or more speeds are used, more switching equipment is necessary to provide for speed changing, but the general system is the same. Where remote control is necessary, the system is somewhat more complicated, but the same general principles apply. Where direct current is used for operating the control, it is necessary to provide no-voltage relays, which will shut down the motor in case either alternating or direct current fails. Special cases, such as concatenated sets, require special arrangement of control.

Direct-current Motors are used only on low-voltage circuits, usually 250 volts, and can be handled by contactors. Quick stops can be accomplished with d-c. motors by dynamic braking, by which the armature is disconnected from the line and connected across a resistance so that the motor becomes a generator. Compound motors should be used with flywheels in order to give automatic reduction in speed as the load increases.

Characteristics of Gary Equipment. — The characteristics of the main-roll motor equipment for the rail, billet, and sheet-bar mills of the Indiana Steel Company, Gary, Indiana, are given in the following table:

CHARACTERISTICS OF MAIN ROLL MOTORS

Rail mill

No. of motors*	H.P.	R.p.m.	Flywheel effect†	Weight complete, pounds
2	2000	214	4,312,000	392,000
1	6000	83	11,600,000	749,000
1	2000	68	8,950,000	578,000
1	6000	88	11,600,000	749,000
1	6000	75	14,100,000	783,000
Billet mill				
2	2000	214	4,312,000	392,000
3	6000	83	11,600,000	624,000
Sheet-bar Mill				
1	6000	83	11,600,000	624,000

* All motors 25 cycles, 6600 volts.
† Weight of flywheel in pounds times square of radius of gyration in feet.

AUXILIARY MOTOR APPLICATIONS.—The application of electric motors for auxiliary steel-mill machinery has been used for a long time. The nature of this service is unusually severe and has led to the development of the mill-type motor for both d-c. and a-c. service. These motors are designed to withstand heavy overloads and abnormally rapid acceleration, and their construction is such that various parts are interchangeable, which greatly facilitates repairs and minimizes the delays incident to the same.

All A-C. versus Mixed System.—Whether a-c. or d-c. motors should be used for driving the auxiliary machinery in a steel mill is a problem which has been very seriously discussed, and has led to the use of two recognized systems. These are known as the all a-c. system, where no direct current is used, and the mixed system, where direct current is used for the small motors.

A great many factors must be considered in comparing the two systems. In the first place, it is to be assumed that power will primarily be alternating-current, as the transmission distances ordinarily preclude the use of direct-current generators. It would therefore seem to be simplest and most efficient to step down to a suitable voltage through static transformers and use alternating-current motors. The mixed system involves additional expense for motor-generator sets and entails considerable power loss due to the low efficiency of conversion. On the other hand, direct-current motors are lower in first cost than induction motors and a higher power factor is maintained on the entire system where they are used. In the mixed system an increase in power factor is effected by eliminating the lagging current of the induction motors, and, in addition, the motor-generator sets can be equipped with synchronous motors which will take a leading current from the line and offset part of the lagging current on the rest of the system. The increase in power factor enables a reduction to be made in the size and cost of transformers and generators, and also increases their efficiency due to the lower currents which they are required to handle and to the decreased excitation required by the generators.

In order to make as nearly as possible a general determination of these factors, an exhaustive study of the problem was made by Messrs. Shover and Cheney and the results presented in a paper before the Association of Iron and Steel Electrical Engineers. (*See also General Electric Review, Aug., 1912.*) The conclusions reached were as follows:

1. The all a-c. system costs slightly more than the mixed system.
    a. First cost higher for 22,000 volt transmission than for 6600.
    b. First cost higher for gas engines than for turbines. From this it appears that the higher the first cost of power supply the less favorable is the use of the all a-c. system.
2. The lower the power factor, the greater is the cost of the all a-c. system for both percentages of auxiliary load.
3. The less the percentage of auxiliary load the less the cost of the all a-c. system for both power factors.
4. The annual costs of the all a-c. system considered are lower than those of the mixed system.
5. The actual operating costs, i.e., excluding interest, depreciation, taxes and insurance, of the all a-c. system are considerably less than those of the mixed system.
6. The cost of maintenance of the mixed system is based on an estimate and not on actual records. Should this item be entirely neglected, the results in nine out of sixteen cases would show an excess of annual costs for the all a-c. system, but the amount is so small that accurate calculations for any individual case would be necessary to determine the relative advantages.

7. When the saving in output due to the reduced delays in the all a-c. system is taken into consideration, the saving in annual costs will be largely increased; and even should the difference in motor maintenance be neglected there would still be a considerable saving in annual costs for the all a-c. system.

In conclusion, then, for a rolling mill properly motored, where the percentage of power required for auxiliary apparatus (exclusive of pumps, etc.) is 25 per cent or less of the total power delivered to that mill, and where the power factor of the entire mill including both main and auxiliary apparatus is 70 per cent or over, the authors feel amply justified in saying that the all a-c. system will show a saving in annual cost, to say nothing of its greater simplicity and more satisfactory operation.

[D. B. RUSHMORE, assisted by E. A. LOF.]

STOKERS, MECHANICAL. — (*See also Boilers.*) Mechanical stokers serve a twofold purpose: they make possible a more uniform and a more complete combustion of the fuel and thereby prevent the formation of smoke, and they also reduce the amount of labor required in handling and firing the fuel. To insure the prevention of smoke a fire-brick arch should also be used over the front part of the furnace.

There are five classes of stokers on the market. (1) The "chain-grate stoker," made by Babcock and Wilcox and others, is a continuous belt of grate bars driven over sprockets at the front and rear of the furnace. Coal is fed continuously upon the grate from the hoppers located above the boiler, is carried by the grate the entire length of the furnace at such a rate that it is completely burned by the time it reaches the back of the furnace. (2) The "front-feed step grate" (the Roney and the Wilkinson stokers) consists of a series of stepped grate bars, slightly inclined from the horizontal, and a dumping grate at the bottom which receives and discharges the ashes. The bars are given a slow rocking or sawing motion by means of a small engine or motor. (3) The "side-feed step grate" (the Murphy stoker) is similar to the front-feed step grate, but is arranged so that the fuel is fed into the furnace from the two sides. (4) The "underfeed stoker" (the Jones and Taylor stokers) pushes fresh coal into the fire from beneath. The volatile matter of the freshly fired fuel then has to pass through a body of ignited coke and is thus heated to the ignition point before coming into contact with the supply of hot air immediately above, where it is rapidly burned. (5) In the "sprinkler type" of stoker the fuel in finely divided form is sprinkled uniformly over the entire grate. In the Little Giant stoker this is accomplished by discharging the coal into a cast-iron chute which extends over the front part of the grate, from which it is blown into the furnace by a steam jet.

COSTS. — The following costs are taken from Gebhardt's *Steam Power Plant Engineering*. Approximate costs of stokers suitable for a Babcock and Wilcox boiler of 350 horse-power capacity; 45 square feet of grate surface; height of chimney above grate, 175 feet; coal burned, Illinois screenings; cost of installation not included:

Chain grate and appurtenances	$1500
Roney stoker	1300
Murphy stoker and furnace	1350
Jones underfeed stoker	1400

The maintenance charge of a chain-grate stoker should not exceed $5 per boiler per year, with proper care, and the stoker should have a life of 15 years. If the stokers are neglected or abused the maintenance charge may be as high as $100 per year. Stokers are often condemned by their owners as inefficient and inferior to hand firing, because no particular attention has been paid to them beyond filling the hopper with coal. They should be operated in strict accordance with the principles of their design.

[Wm. Kent.]

STRENGTH AND ELASTICITY. — (*See also Buildings, Allowable Unit Stresses in; Mechanics, Principles of; Structures, Simple.*) When opposing external forces are applied to a body the latter is in general deformed more or less, and, in the case of solids, when the applied forces are increased sufficiently the body ruptures.

STRESSES. — A stress is the internal resisting force set up within a body opposing the external forces which tend to deform it. When the external forces cause a stretching of the body the stress is called a tension; when the external forces compress the body the stress is called a compression; when the external forces cause a relative slipping of the particles in two contiguous parallel planes in the body the stress is called a shear.

Unit Stress. — By unit stress is meant the stress per unit area; in the case of tension or compression the area is taken perpendicular to the line of action of the forces producing the stress; in the case of shear the area is taken parallel to the forces producing the stress. Unless otherwise stated the stress is assumed uniformly distributed over the area upon which it acts.

Ultimate Stress or Ultimate Strength. — The ultimate stress which a body will stand, or the ultimate strength of the body, is the greatest stress which can be produced in the body without rupturing it. Ultimate strength for tension and compression are usually quite different; the former is usually called tensile strength and the latter compressional strength. The ultimate strength of materials is usually specified in terms of the stress per unit area; see *Units and Conversion Factors.*

DEFORMATIONS OR STRAINS. — The deformation accompanying any stress is usually called a strain. The strain corresponding to a tension is called an elongation, the strain corresponding to a compression is a shortening, the strain corresponding to a shear is called a detrusion. An elongation is usually specified as the ratio (or percentage) of the increase in length to the original length of the specimen. For example, if a rod 10 feet long is stretched by an applied force to a length of 10.2 feet, the elongation is $(10.2-10)/10 = 0.02$ or 2 per cent. The term elongation is frequently used to designate specifically the *maximum* elongation just before rupture.

Hooke's Law. — Experiment shows that when the unit stress in a body does not exceed a certain value it bears a constant ratio to the resulting unit strain (ratio of change in size to original size). This fact is known as Hooke's Law. In the case of a tension the change in size is usually taken as the change in length, no attention being paid to the decrease in cross-section, which is usually negligible, except just before rupture.

ELASTICITY. — A body deformed under stress will return to its original shape when the stress is removed, provided it has not been strained beyond the point at which the proportionality between stress and strain ceases. This ability to return to its original form after deformation is called elasticity.

Elastic Limit. — The stress per unit area corresponding to the point at which the proportionality between stress and strain ceases is called the elastic limit of the material.

Permanent Set. — When a body is stressed beyond its elastic limit, the deformation per unit increase in stress becomes greater than it was before this point was reached, and the material takes a permanent "set," i.e., when the stress is removed the body does not return to exactly its original form. As a measure of the "set" is taken the ratio of the permanent change in size (after the stress is removed) to the original size.

Modulus of Elasticity. — Let ΔF denote the change in the total tension producing a change Δl in a rod of length l and cross section A; then the quotient of the increase in the unit stress by the increase in the elongation per unit length, is called the modulus of elasticity (Young's modulus) of the material, and may be designated by the symbol M, i.e.,

$$M = \frac{\Delta F}{\Delta l} \cdot \frac{l}{A}.$$

This modulus has the dimensions of pounds per square inch.

VALUES OF TENSILE STRENGTH AND MODULUS OF ELASTICITY.— Values of these properties given by different authorities are extremely variable, since the measured values depend largely upon the chemical composition, heat treatment, age, size and shape of the test specimen.

Alloys, Miscellaneous.— See articles on *Alloys* and *Wires, Resistance.*

Aluminum. — See article on *Aluminum.*

Belting. — Tensile strength, in pounds per square inch: Cotton, 4500 to 8900; Single leather, 3200 to 5900; Double leather, 2200 to 5400. See also article on *Belts and Belting.*

Brass Wire. — Tensile strength ranges from about 50,000 to 150,000 pounds per square inch; modulus of elasticity is about 14×10^6 pounds per square inch.

Brick. — See article on *Bricks and Brick Masonry.*

Bronze Wire. — The tensile strength of phosphor-bronze wire ranges from about 44,000 to 140,000 pounds per square inch; of silicon-bronze wire, from 95,000 to 115,000 pounds per square inch.

Cement. — See article on *Cement.*

Concrete. — See article on *Concrete.*

Copper. — See articles on *Copper* and *Wires and Cables, Bare.*

Earth. — See *Soils,* below.

Glass.—Tensile strength of common green or of flint glass ranges from about 2500 to 5000 pounds per square inch. Modulus of elasticity ranges from about 8.5×10^6 to 11.5×10^6.

The crushing or compressive strength of glass ranges from about 13,000 to 40,000 pounds per square inch.

Granite. — Crushing or compressive strength ranges from about 9700 to 34,000 pounds per square inch.

Iron. — See articles on *Iron, Pig and Cast,* and *Iron, Wrought.*

Lead. — Tensile strength ranges from about 2600 to 3300 pounds per square inch.

Limestone. — Crushing or compressive strength ranges from about 6000 to 25,000 pounds per square inch.

Marble. — Crushing or compressive strength ranges from about 7500 to 21,000 pounds per square inch.

Nickel. — Tensile strength of cast nickel ranges from about 40,000 to 85,000 pounds per square inch, and tensile strength of annealed nickel ranges from about 70,000 to 95,000 pounds per square inch. Modulus of elasticity ranges from about 24×10^6 to 27×10^6 pounds per square inch.

Rope. — See *Ropes and Rope Drive.*

Soils. — See articles on *Power Stations, Hydroelectric,* and *Buildings, Allowable Unit Stresses in.*

Steel. — Tensile strength in pounds per square inch:

Bessemer:	56,000 to 74,000,	Open-hearth:	50,000 to 69,000,
Cast:	67,000 to 106,000,	Wire:	50,000 to 450,000.

Modulus of elasticity of various kinds of steels usually ranges between 27×10^6 and 35×10^6 pounds per square inch. See also articles on *Steel* and *Wires and Cables, Bare.*

Timber. — See articles on *Timber* and *Poles for Overhead Lines.*

Tin. — Tensile strength ranges from about 4000 to 5000 pounds per square inch; modulus of elasticity from about 2.5×10^6 to 6×10^6 pounds per square inch.

Zinc. — Tensile strength ranges from about 7000 to 30,000 pounds per square inch; modulus of elasticity is about 12×10^6 pounds per square inch.

Wood. — See *Timber,* above.

[H. PENDER AND R. G. HUDSON.]

STRUCTURES, SIMPLE. — (*See also Building Laws; Cement; Concrete; Iron; Mechanics, Principles of; Steel; Timber; Towers for Transmission Lines.*) A structure in the sense used by engineers is a member or combination of members constructed to hold forces in equilibrium. The common structures are beams, girders, columns and trusses.

A brief outline of the contents of this article is as follows:

DEFINITIONS AND FUNDAMENTAL RELATIONS. — The more common terms used in the treatment of structures are defined below.

Center of Gravity; Moment of Inertia; Radius of Gyration; Stress and Strain. — See *Mechanics, Principles of.*

Neutral Axis. — The neutral axis of the cross-section of a stressed bar is the locus of those points in the plane of the cross-section at which the direct fiber stress equals zero. If the bar is of homogeneous material and subjected to flexure (*see Bending Moment, below*) only, the neutral axis passes through the center of gravity of the cross-section, and if the loads causing flexure are applied in the plane of one of the principal axes, the neutral axis coincides with the other principal axis. This is the condition commonly occurring in wooden and steel beams. Table I which follows gives the location of the neutral axis for such cases only. If the cross-section is subjected to combined flexure and direct stress, the neutral axis will not pass through its center of gravity, but will deviate from it by an amount depending upon the ratio of bending moment to direct stress, reaching infinity when the stress is direct tension or compression only, as in the case of a tie rod or column centrally loaded.

If the beam is of unhomogeneous material the position of the neutral axis must be determined by calculation. The reinforced concrete beam is the only common example of such a case. For formulas for this case, see *Concrete, Reinforced.*

Section Modulus. — If c is the normal distance from the neutral axis of a given plane surface to the most remote portion of its perimeter, and I the moment of inertia of the surface about its neutral axis the expression I/c is called the section modulus. For symmetrical beams exposed to pure flexure only, c = one-half the depth of the beam. Tabular values of this quantity for plane surfaces of varying shapes are given in Table I and for the ordinary structural steel beams in Tables III to VI, which follow.

Moment of Resistance. — If s is the allowable unit stress per square inch upon the extreme fiber of a beam or girder, the expression $\frac{sI}{c}$ is called the moment of resistance since its value equals the maximum bending moment which the member may carry without causing a stress greater than the allowable unit stress.

Statical Moment. — The statical moment of a plane surface about a given axis lying in the plane is the summation of the products of each elementary area,

dA, of which the surface is composed, times the distance of its center of gravity from the given axis, distances above the axis being considered positive, and below negative. It may be expressed mathematically as follows: (See Fig. 1.)

Let Q = statical moment of a given area about an axis Y-Y lying in the plane of the area,

dA = an elementary area,

y = distance of center of gravity of the area dA from the axis,

then $Q = \int y dA$.

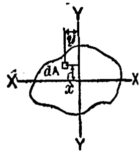

Fig. 1.

The statical moment of an area about an axis of symmetry evidently equals zero since the positive lever arm of any elementary area will be balanced by a corresponding negative lever arm.

Equations of Equilibrium. — (*See also Mechanics, Principles of.*) The following laws apply to a structure lying in a plane and acted upon by forces lying in the same plane:

1st. The algebraic sum of the components of all the forces acting parallel to any axis in the plane of the forces must equal zero.

2nd. The algebraic sum of the moments of all the forces about any axis at right angles to the plane of the forces must equal zero.

If we resolve the applied forces into components parallel to two rectangular axes, OX and OY, and let ΣX and ΣY equal the algebraic sum of the forces parallel respectively to OX and OY, and ΣM the algebraic sum of their moment about any axis, normal to the plane of the forces, these two laws will be fully comprehended by the three equations:

$$\Sigma X = 0, \ \Sigma Y = 0, \ \Sigma M = 0.$$

If OX and OY are respectively horizontal and vertical these equations take the generally used form:

$$\Sigma H = 0, \ \Sigma V = 0, \ \Sigma M = 0.$$

Unless a structure satisfies all these conditions it cannot be in equilibrium.

Reactions. — The forces which the abutments or piers exert upon structures, such as beams, girders or trusses, are called the reactions. Each reaction may, in general, have three unknown factors, viz., direction, magnitude and point of application. In order to simplify computations it is customary for girders or trusses to eliminate three of these unknowns by the method of construction; e.g., in end-supported trusses and long girders, the ends are usually supported on pins of comparatively small diameter thereby fixing the points of application of both reactions. Moreover, the pin at one end is in turn supported on a set of rollers thereby making that reaction normal, or nearly so, to its supporting surface, thus fixing the direction of one of the reactions. These refinements are not generally applied to short girders the ends of which are supported on steel plates or castings. Even in such cases, however, the point of application is fixed within comparatively small limits, and the base plate at one end is usually planed thus making the reaction at that end approximately normal to the supporting surface. For ordinary beams no special provision is made to fix any of the reaction conditions but each reaction is assumed to be normal to the supporting surface and to act at its center.

When the unknown reaction factors are thus reduced to three, their values may be determined by the three equations of equilibrium previously given, this being the usual procedure in the case of beams on two supports as illustrated later. For beams supported at more than two points, the three-moment equation (*see below*) may be applied.

Three Moment Equation. — This is an equation connecting the moments at three adjoining points of support of a continuous structure. It is strictly applicable only to structures having a constant moment of inertia and on level supports but is applied approximately to structures the moment of inertia of which is not constant.

The formula for concentrated loads is as follows:

Let M_c = moment at any support,
M_a = moment at adjoining support on left,
M_b = moment at adjoining support on right,
L_1 = length of span to left of support at which M_c acts,
L_2 = length of span to right of support at which M_c acts,
P_1 = any load in span L_1 and k_1L_1 its distance from left support,
P_2 = any load in span L_2 and k_2L_2 its distance from support at left of that span.

Then

$$M_aL_1 + 2\,M_c(L_1 + L_2) + M_bL_2 = \Sigma P_1L_1^2(k_1^3 - k_1) + \Sigma P_2L_2^2\,(3\,k_2^2 - k_2^3 - 2\,k_2).$$

For uniform load of w_1 lb. per ft. over span L_1 and w_2 lb. per ft. over span L_2 the preceding formula becomes

$$M_aL_1 + 2\,M_c(L_1 + L_2) + M_bL_2 = -\frac{1}{4}w_1L_1^3 - \frac{1}{4}w_2L_2^3.$$

The application of these formulas to successive series of spans enables the moments at all supports to be computed and from these the reactions and shears may also be determined, and the structure completely solved; see section below on *Girders, Design of.*

Shear. — The shearing force or shear at any section of a body is the force which tends to produce slipping along the given section. Shearing failure may be due either to transverse fracture or to slipping of the fibers on each other. Of the ordinary structural materials wood is the only one of fibrous character and shearing failure in this material frequently occurs on planes parallel to the fibers.

Bending Moment; Flexure. — The bending moment at any section of a body due to a set of coplanar forces is the resultant moment about an axis passing through the center of gravity of the section of all the forces on either side of the section, it being understood that the section and the axis are perpendicular to the plane of the forces. Fractures due to excessive bending moment occur through longitudinal failure of the fibers either by tension or crushing. The bending which results from the application of a bending moment is termed flexure.

Dead and Live Loads. — The loads acting upon a given structure may be divided into two distinct types: viz., quiescent loads which are known as *dead loads* and moving or intermittent loads which are known as *live loads.* The first class includes all loads which are fixed in magnitude and position such as the weight of the structure itself and such superimposed loads as the floor of a building or bridge; the second class includes such loads as crowds of people, merchandise, snow, wind and vehicles of all sorts. The live load through its rapidity and irregularity of application is more injurious in its effect than the dead load, hence in a structure subjected to live loads, either the value of the live load should be increased as explained below under *Allowances for Impact,* or the allowable unit stress in the material should be reduced. The former method seems to be more logical and is commonly adopted at the present time by leading structural engineers.

(Text continued on p. 1428.)

TABLE I.—PROPERTIES OF SECTIO

Section. Axes $X-X$ and $Y-Y$ pass through center of gravity	Distance from $X-X$ to extreme edge of section c	Moment of inertia with respect to axis $X-X$ I_x	Section modulus with respect to axis $X-X$ $\frac{I_x}{c}$	Radius of gyration with respect to axis $X-X$ ρ_x

Impact is the name given to the dynamic force which is added to the forces due to live and dead loads to obtain the true forces acting upon structures; see section below on *Allowances for Impact.*

Beam or Girder. — A beam is a bar of wood, metal, concrete or other stress-resisting substance supported at certain definite points along its length and loaded transversely to its longitudinal axis, which is usually but not always, placed in a horizontal position. The name girder is commonly applied to large beams built up of structural members; for example, a plate girder is a steel or iron structure made up of plates and angles, or other structural shapes, riveted together.

Floor Beam; Panel.—Frequently girders and trusses receive all their live load and much of their dead load through other members called floor beams. Fig. 2 illustrates such construction. The distance between adjacent floor beams is the panel length.

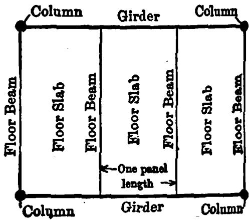

Fig. 2.

Column. — A column is a member intended primarily to resist direct compression, although it may also be subjected to bending stresses due either to transverse loads or to eccentric application of the direct loads.

Truss. — A truss is a structure consisting of separate bars constructed to carry either direct tension or direct compression. These bars are connected at their ends and occasionally at intermediate points, the points of connection being called joints. The connections are sometimes made by riveting the bars directly together and sometimes by riveting them to a common steel plate, the truss in either case being called a *riveted truss.* The connections may also be made by fastening together with a large steel pin all the members meeting at a joint; such a truss is called a *pin truss.* The outer forces should be applied at the joints only, since the members are not intended to carry bending. This is accomplished by the use of floor beams in a bridge and purlins in a roof.

PROPERTIES OF PLANE SECTIONS. — In Table I are given the location of the center of gravity, and values of the moment of inertia, section modulus and radii of gyration of the more common plane sections.

TABLES OF STRUCTURAL SHAPES.—Tables II to VI give the dimensions and properties of the commonly used shapes of structural steel; namely, sheared plates, angles with either equal or unequal legs, I-beams, and channels. For information upon other metallic structural material see the publications of the various steel manufacturing companies.

* Divide by span in feet to determine total allowable dead load in pounds, including weight of beam, uniformly distributed over length of beam. Table is based upon a fiber stress of 16,000 lb. per sq. in. For allowable live and dead load reduce load as determined from table by amount of impact. Compression flange should be supported laterally at intervals not greater than 20 times its width. If this cannot be done reduce coefficients to one-half of above value where unsupported length divided by width = 70, and proportionally for intermediate values between 20 and 70.

ALLOWANCES FOR IMPACT. — The force applied to a structure by a moving load such as a locomotive or electric car is a function of its weight and method of application. The value of the former can usually be determined with a reasonable degree of accuracy; the effect of the latter cannot in general be so determined since it depends upon such uncertain factors as rapidity of application, irregularity of track, improper counterbalancing of locomotive driving wheels, swaying action of crowds of people and similar causes. The allowance for impact (so-called) ranges from 0 to 100 per cent of the live load and is determined by empirical rules as indicated in the formulas below. An exception to this rule is made in the case of timber structures where the effect of impact is commonly allowed for by using a low unit stress. (*See Timber.*)

Impact on Buildings. — No allowance is generally made for impact on buildings except with special loadings such as moving machinery, swinging cranes, etc., for which the designer should use his judgment. The building laws of the larger cities fix arbitrary loads and unit stresses by which the designer must be governed; see article on *Buildings, Allowable Unit Stresses in.*

Impact on Highway Bridges Carrying Electric Railways. — The following extract from the *Specifications for Bridges Carrying Electric Railways* adopted by the Massachusetts Railroad Commission may be safely used for such cases.

"The total maximum stress in any piece shall be computed by adding together the dead and live stresses, the live loads being placed in the most unfavorable position, together with a percentage of the live stress to allow for impact and vibration. This added percentage shall be as follows:

For floor beams and stringers	25 per cent
For floor beam hangers	40 per cent
For all counters	40 per cent

For other members in trusses, and for main girders:

When the "loaded length" is 20 feet or less	25 per cent
When the "loaded length" is 200 feet or more	10 per cent

and proportionally for intermediate lengths."

Impact on Steam Railroad Bridges. — The following rule of the American Railway Engineering and Maintenance of Way Association is commonly used in the United States:

"The dynamic increment of the live load shall be added to the maximum computed live-load strains* and shall be determined by the formula $I = S\dfrac{300}{L + 300}$,

where I = impact or dynamic increment to be added to live-load strains,
S = computed maximum live-load strain,
L = loaded length of track in feet producing the maximum strain in the member.

For bridges carrying more than one track, the *aggregate length of all tracks* producing the strain shall be used. Impact shall not be added to strains produced by longitudinal, centrifugal and lateral or wind forces."

CALCULATION OF REACTIONS. — The reactions upon a truss, girder or beam lying in a plane and acted upon by forces lying in the same plane may be determined by the application of the equations of equilibrium (*see preceding section*) provided there are but two reactions which together have three unknown components; such a structure is said to be statically determined. If more than three unknown reaction components exist the reactions cannot be computed by statics, and the structure, although stable, is statically undetermined; if less than

* Strains as here used means stresses in the more modern meaning of the words.

three exist the structure is unstable. If the structure is supported at more than two points it cannot be made statically determined except by the insertion in the structure of special devices, such as hinged joints. The tower shown in Fig. 3 is statically determined with respect to the outer forces since the points of application of the reactions at a and b are fixed in position, and the reaction at b is also fixed in direction. If neither of the reactions were fixed in direction the structure would be indeterminate; if both of the reactions were fixed in direction the tower would be unstable, e.g., if both ends were on rollers and neither end bolted to the masonry.

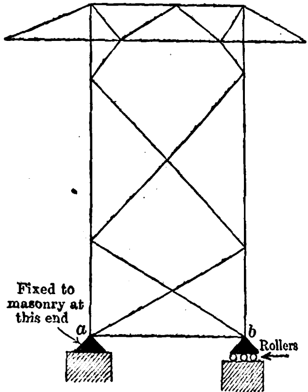

Fig. 3.

Such towers when used for transmission lines are seldom built with rollers or even planed plates, and frequently the bottoms of the columns are imbedded in a concrete base, the latter condition making it impossible to accurately compute the reactions. Similar towers for railroad and highway bridges are usually made determinate.

Method of Computation. — The following example illustrates the analytical method of computing reactions on statically determinate structures. The method may be applied equally well to uniformly distributed loads provided the resultants of such loads are used in place of concentrated loads.

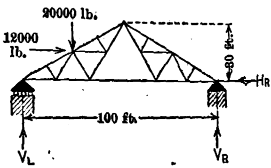

Fig. 4.

To Compute the Reactions on Truss Shown in Fig. 4. — Let V_L = left reaction, and V_R and H_R = the components of the right reaction, the direction of which is unknown. V_L will be vertical since it is supported on rollers bearing on a horizontal surface. V_R and V_H may be assumed to act in either direction. A negative sign in the final result indicates that the force acts in the opposite direction to that assumed. The determination of the reactions by the application of the equations of equilibrium (*see above*) may be carried out as follows:

1st. Apply $\Sigma M = 0$ about right end. This gives $100\,V_L + 12{,}000 \times 15 - 20{,}000 \times 75 = 0$. Hence $V_L = 13{,}200$ lb.

2nd. Apply $\Sigma H = 0$. This gives $H_R - 12{,}000 = 0$. Hence $H_R = +\,12{,}000$ lb.

3rd. Apply $\Sigma V = 0$. This gives $V_R + 13{,}200 - 20{,}000 = 0$. Hence $V_R = +\,6800$ lb.

In these results a positive sign shows that the reaction acts as indicated in Fig. 4.

Reactions on Continuous Girders. — See sections which follow on *Continuous Girders, Beams, Slabs* and *Trusses.*

CALCULATION OF SHEAR. — The nomenclature used in the discussion of shear is as follows:

V = the total external shear on any section in pounds,
P = magnitude of a single concentrated load in pounds,

w = a uniform load in pounds per foot,
L = span of beam in feet (distance center to center of supports),
p = length of a panel in feet,
x = distance in feet from a given section to one of the points of support,
n = total number of equal panels into which a girder is divided,
z = number of panels between a given panel and the more remote abutment.

Method of Computation. — The magnitude of the shear at any section of a body due to a set of coplanar forces may be readily computed in the following manner: Resolve each force into two components, parallel and perpendicular respectively to the given section; the algebraic sum of the components parallel to the section of all the forces on either side of the section equals the shear. The shear is generally considered positive when the resultant force is *upward* on the *left* of the section.

Curve of Shear. — A curve of shear is a line the ordinate to which at any point equals the shear on the given body at the section where the ordinate is measured. Fig. 5 shows typical curves of this sort.

Maximum Shear with Single Load or Uniform Load. — In a simple end-supported beam, girder or truss a concentrated load causes maximum shear at a given section when placed an infinitesimal distance from the section on the side toward the more distant point of support; the magnitude of this shear equals that of the nearer reaction. A concentrated load causes a maximum shear on the beam when placed an infinitesimal distance to one side of either point of support; this shear equals the magnitude of the load itself. A uniformly distributed live load causes maximum shear at a given section when placed over the entire distance from the section to the more distant point of support; its value equals that of the nearer reaction and is given by the equation $V = wx^2/2L$. Its maximum value equals $wL/2$ at either end of the beam when the latter is fully loaded.

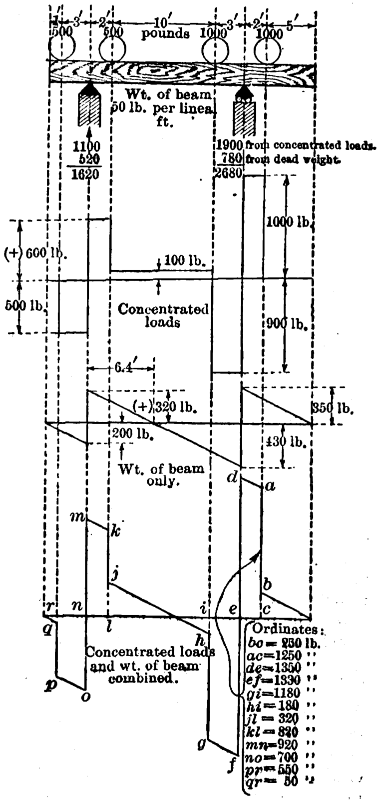

Fig. 5. Curves of Shear. Positive results are shown above the axis. Curve shown by full line

End-supported Girders or Trusses with Loads Applied by Floor-Beams. — A concentrated load causes maximum shear in any panel when

placed at the end of the panel nearer the more remote reaction. The value for equal panels is given by the equation $V = Pz/n$. The maximum shear occurs in the end panel and its value for equal panels is $V = P\ (n - 1)/n$.

Maximum positive shear in any panel due to uniform load occurs when all panel points to the right are assumed to be loaded with full panel loads, and all panel points to the left are unloaded; its value equals the left reaction. This method is approximate but is on the safe side and is commonly used.

The maximum positive shear occurs in the left panel and for girders with equal panels is given by the formula:

$$V = \frac{wp}{2}(n - 1).$$

The same rules are applicable for the maximum negative shear by interchanging left and right in the discussion.

Computation of Maximum Shear for System of Concentrated Loads. — The shear at any section of a beam, girder or truss, due to a system of concentrated loads such as wheel loads of a moving crane, electric car or electric locomotive, equals the algebraic sum of either reaction and the loads lying between that reaction and the given section. In case the girder is divided into panels and the shear in a given panel is to be computed, only that portion of the load acting in the panel under consideration which is carried by the floor-beam at the end of the panel nearer the selected reaction should be deducted from the reaction. To determine the position in which a system of concentrated loads should lie to give maximum shear it is often necessary to proceed by trial. The use of the following simple rules may be helpful.

(*a*) The maximum shear at a given section of a simple beam always occurs with one of the loads at an infinitesimal distance to one side of the section. This load should usually, but not always, be one of the heavier loads of the system; e.g. one of the driving wheels of a locomotive. The proper load may be determined by starting with the first load just to the left of the section and moving the loads to the left until $\sum \frac{Pa}{L} \eqsim P'$. In this expression $P =$ any load which may be on the span during the process of moving the loads, and a is the distance which it is moved. $P' =$ the load which passes to the left of the section as the loads are moved from one position to another.

(*b*) The maximum shear in a given panel of a girder always occurs with one of the loads directly over one of the adjoining floor-beams. This load should usually, but not always, be one of the heavier loads.

(*c*) The position of the loads for maximum positive shear in an intermediate panel may be determined as follows. Place the first load of the system at the right end of the panel and move the system to the left until $\sum \frac{Pa}{L} \eqsim \sum \frac{P_1 a_1}{p}$. Apply the same criterion to the second load and following loads until the position giving maximum shear is reached. In the above expression, P and a are as before, $P_1 =$ any load which may be at any time in the panel under consideration during the process of moving the loads, and $a_1 =$ the distance which P_1 may move in the panel.

If no load comes on or goes off the span and if no load passes out of the panel, $a = a_1$ and we may write

$$\sum \frac{P}{L} \eqsim \sum \frac{P_1}{p}.$$

It follows that for this case the first load should lie at the panel point unless the average load per foot on the entire span is greater than the first load divided by a panel length, in which case the second load should be tried at the panel point and so on until the position for maximum shear is determined.

(*d*) The maximum shear in the end panel of a girder equals the maximum moment at the first panel point divided by the length of the panel. (*See section on Bending Moment, below.*)

CALCULATION OF BENDING MOMENT. — The nomenclature used in the discussion of bending moment is as follows:

M = external bending moment at any section in foot pounds,
P = magnitude of a single concentrated load in pounds,
w = a uniform load in pounds per foot,
L = span of beam in feet (distance center to center of support),
p = length of a panel in feet,
x = distance in feet from a given section to one of the supports,
n = total number of equal panels into which a given girder is divided.

To determine the magnitude of the bending moment at a given section it is necessary to obtain the algebraic sum of the products of every force by its distance from the neutral axis of the section. A mistake commonly made is the failure to consider all the forces, particularly horizontal forces. The moment is considered positive if it is clockwise on the *left* of the section; it follows that the moment is also positive if it is counter-clockwise on the *right* of the section.

Curve of Moments. — A curve of moments is a line whose ordinate at any point equals the moment on the given body at the section where the ordinate is measured. Fig. 6 shows a typical set of moment curves.

Maximum Moment with Single Load or Uniform Load. — For simple end-supported beams, girders and trusses a single concentrated load causes maximum moment at a given section when placed at the section. The following formula gives its value:

$$M = \frac{P(L-x)}{L}x.$$

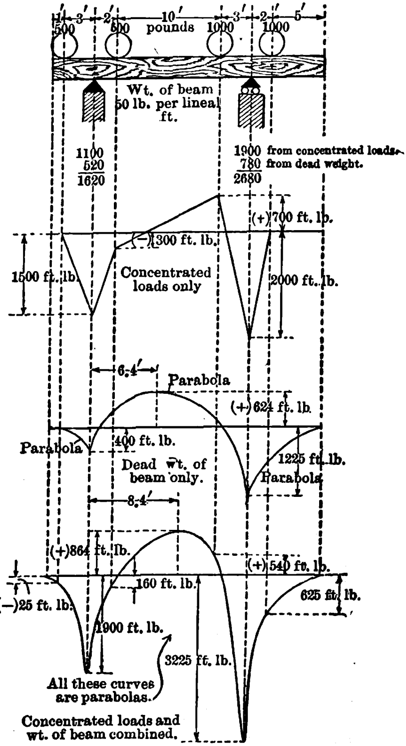

Fig. 6. Curves of Moments

The maximum possible moment occurs when $x = L/2$ and has the value $M = PL/4$.

For simple end-supported structures a uniform load causes maximum moment at any section when it covers the entire beam. Its value at any section is

$$M = \frac{wx}{2}(L-x).$$

The maximum possible moment occurs at the center of the span and equals $wL^2/8$.

End-supported Girders or Trusses with Loads Applied by Floor-Beams. — Moments at panel points are exactly the same as moments at corresponding points on simple girders. It is seldom necessary to consider moments between panel points for concentrated loads. For a uniform load the moment between floor-beams varies uniformly; i.e., the moment due to that portion of the load applied through the floor-beams.

The maximum moment due to a concentrated load occurs at the panel point nearest the center with the load at that point. Its value is given by the following equations:

For even number of equal panels, $M = \frac{Ppn}{4}$.

For odd number of equal panels, $M = \frac{Pp}{4n}(n^2 - 1)$.

The maximum moment due to a uniform load occurs at the panel point nearest the center with load over entire span. Its value is:

For even number of equal panels, $M = wL^2/8$.

For odd number of equal panels, $M = \frac{1}{8}\left[wL^2\left(1 - \frac{1}{n^2}\right)\right]$.

Computation of Moment for System of Concentrated Loads. — The moment at any section due to a system of concentrated loads, such as wheel loads of a moving crane, electric car or electric locomotive equals the algebraic sum of the moments of either reaction and the loads lying between it and the given section, the lever arm for each load being its distance from the section. In case the girder is divided into panels and the section under consideration is at some intermediate point in a panel only that portion of the load applied in this panel which is transmitted to the girder by the floor-beams between it and the reaction used should be considered.

Determination of Maximum Moment at a Given Section. — The maximum moment at any section of a simple beam or at any panel point of a girder loaded through floor-beams always occurs with some load at the section (usually one of the heavier loads). This load should be one which when located just to the right of the section makes the average load per foot of all the loads on the span to the right of the section greater than the corresponding average load per foot on the left of the section, and which reverses this condition when placed just to the left of the section. Such loads may be selected by trial; if more than one satisfies this criterion the largest moment must be determined by actual computation.

Determination of Position of Maximum Moment on a Beam. — Previous articles deal with maximum moment at a given section. The maximum moment on a beam caused by a system of concentrated loads usually occurs near the center but not at it. The following method may be used to determine the location of the section at which the maximum moment occurs:

(*a*) Select, by inspection, one of the heavier loads which would probably be located at the center to give the maximum moment at the center.

(*b*) Determine by inspection the loads which would be on the span when this load is near the center and compute the position of their resultant.

(*c*) Place the loads on the beam in a position such that the center of the span lies half way between this resultant and the assumed load. If the loads on the span in this position correspond to those assumed under *b*, the moment at the load should be computed; otherwise, another trial may be made. If more

than one set of loads corresponds to this condition the moment at the load should be computed for both sets of loads.

(*d*) Apply the same method to any other load which would possibly give maximum moment at the center.

Since the maximum moment at any section always occurs with some load at the section this method if applied to enough loads will give the absolute maximum moment. It is often unnecessary to try more than one load, and seldom more than two. It should be noted that with two equal loads such a distance apart that with one at the center the other will not be on the span, but that with the center of the span midway between the resultant and one of the loads both will be on the span, the maximum moment may possibly occur with either condition, both of which should be investigated.

BEAMS; FORMULAS AND COSTS. — The effect of the external forces upon any cross-section of a simple beam is to cause bending moment and shear, the former usually being the predominant factor in determining the size of the beam. If the beam is subjected to axial forces as well as transverse forces, it becomes a combination of beam and column, or beam and tie, and can no longer be considered as a simple beam. If a beam has an end which

Fig. 7.

projects beyond its adjoining point of support, it is called a *cantilever beam*, the over-hanging end forming the cantilever portion. A beam supported at more than two points of support is a *continuous beam*. A beam having one or both ends rigidly fixed either by being built into a wall, or by being fastened to another member is called a *fixed ended beam*. Fig. 7 represents all of these types.

Beam Formulas for Ordinary Cases. — As a preliminary step in the design of beams, it is necessary to determine the maximum value of the external bending moments, shears and reactions on the beam by the methods given in the sections above which deal with these subjects inclusive. With these items determined, the following formulas of mechanics (*see Mechanics of Materials, Merriman, 10th Edition, Arts. 41 and 108*) may be employed for the design of beams of ***symmetrical section*** and ***homogeneous material*** loaded with ***transverse loads*** applied in the ***plane*** of one of the ***principal axes***. For the treatment of beams of unhomogeneous material (reinforced concrete) see article on *Concrete*.

Let M = maximum external bending moment on beam in inch-pounds,
I = moment of inertia in (inches)^4 about the neutral axis lying perpendicular to the plane of the external loads. (This axis in a symmetrical beam lies at mid-height.)
c = distance in inches from neutral axis to extreme fiber, equals one-half the depth for symmetrical beams,
s = allowable value of fiber stress (working value),
Q = statical moment about the neutral axis of that portion of the cross-section lying above the neutral axis,
v = allowable intensity of longitudinal shear in lb. per sq. inch,
V = maximum external shear on beam in pounds,
b = thickness of beam at neutral axis.

Then,
$$M = \frac{sI}{c} \qquad \frac{I}{c} = \frac{M}{s},$$

and
$$v = \frac{VQ}{bI} \qquad \frac{Q}{bI} = \frac{v}{V},$$

Steel Beams. — Such beams are made in the shape of the letter I in order to obtain maximum strength for a given amount of material. They are rolled to desired shape and size while hot. For dimensions, allowable loads and properties of the standard sizes made in the United States see Table V above. In addition to the I-beams listed in the table of standard I-beams which are manufactured by all the leading structural steel makers, the Bethlehem Steel Co. manufacture certain special beams of the same general shape but either of greater depth or with wider flange, and the Carnegie Steel Co. also manufacture certain special types of beams. These beams may often be used to great advantage.

Cost of Steel Beams. — The cost of steel beams in place depends upon the cost of transportation, punching, riveting and other necessary shop work and the cost of erection and painting. The base price at the mills is quoted each week in the *Iron Age;* the figures which follow came from the issue of June 19, 1913, and are more representative of average prices than those at the date (August, 1914) of publication of this book.

I-beams under 15 in., 1.45¢ to 1.50¢ per lb.
I-beams over 15 in., 1.55¢ to 1.60¢ per lb.
H-beams over 18 in., 1.55¢ to 1.60¢ per lb.
For cutting to length, under 3 ft. to 2 ft. inclusive, 0.25¢ per lb.
For cutting to length, under 2 ft. to 1 ft. inclusive, 0.50¢ per lb.
For cutting to length, under 1 ft., 1.55¢ per lb.
No charge for cutting to lengths 3 ft. and over.

For total cost in place an estimate of 3 cents per pound is ordinarily safe.

PLATE GIRDERS; FORMULAS AND COSTS. — A typical plate girder with the various parts is shown in Fig. 8. Plate girders are used for openings

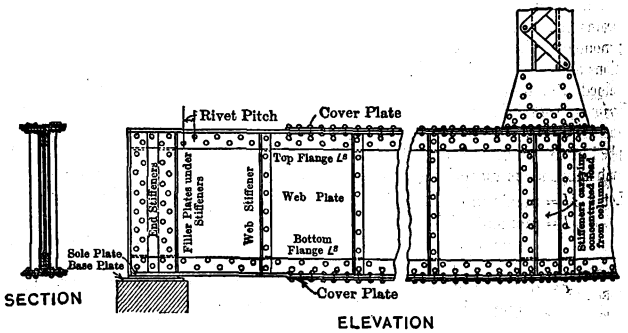

Fig. 8. Typical Plate Girder

where either the load to be carried is too heavy or the clear span too great to be spanned with safety by rolled beams. The maximum length and depth are limited by the possibility of transportation. Probably the largest girder yet made was designed for the Boston & Albany Railroad for use at Worcester, Mass. It is 122 feet 6 inches long, 10 feet 11½ inches deep, and weighs 170 tons. The ordinary and economical depth of plate girders is from ⅙ to 1/12 the span; ⅛ the span is a common value. The maximum depth is usually restricted to 10 feet 6 inches or less.

Essential Points in Plate-Girder Design are as follows:

a. The determination of area of web required to carry the maximum external shear.

b. The determination of area of flange required to resist the maximum external bending moment.

c. The determination of the flange rivet spacing necessary to transmit the flange stress from web to flange.

d. The determination of spacing and size of stiffeners required to prevent the web plate from buckling sidewise, and of size of stiffeners at all points of application of concentrated loads together with number of rivets required therein.

e. The determination of length of flange cover plates.

f. The design of splices for web, angles and cover plates.

g. The design of bearing plates to transmit end reactions into masonry.

It is impossible to give in the limited space available here the necessary formulas and data for the design of plate girders. For further information see Spofford's *Theory of Structures*, N. Y., 1911.

Design of Box Girders. — Box girders resemble plate girders, but have two or more webs as indicated in Fig. 9. They are used where conditions require a shallow girder of great strength. The rules applicable to plate girders apply in general to box girders, but owing to their shallow depth it is usually advisable to determine their strength against bending by the general beam formula $M = \frac{sI}{c}$, the moment of inertia being computed with due allowance for rivet holes (*see Spofford's Theory of Structures, N. Y., 1911, Art. 62 and 63*). The shear in a two-web girder may be considered as equally divided between the two webs, and in a three-web girder as carried half by the center web and half by the two side webs combined. The flange rivets, stiffeners, etc., should be computed on the same basis.

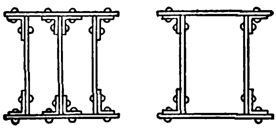

Fig. 9.

Cost of Girders. — The cost of girders is usually computed on a cent-per-pound basis. Price of girders erected in place and painted usually ranges in the Eastern states from 2½ to 4 cents per pound, depending upon the state of the market, location, amount and complexity of the work, rigidity of specifications and inspection, cost of maintaining traffic (in railroad work), etc. The price of 3½ cents per pound may be considered a fair average allowance for approximate estimates. In the West this figure should be materially increased to cover the additional freight rate from Pittsburgh or Chicago.

For basic prices of material see below under *Price of Structural Material*. For freight rates to various points from Pittsburgh, see below under *Freight Rates*.

COLUMNS; FORMULAS AND COSTS. — Steel columns may be made of single rolled sections such as I-beams or channels, or of compound sections consisting of single sections riveted together. A typical steel column is shown in Fig. 10. Single sections of steel columns should be limited in length for convenience in erection and economy in shipment to 60 feet over all or even less. Lengths up to 120 feet may, however, be shipped in one piece if necessary.

Cast-iron columns are made by pouring liquid iron into molds. They may be of various shapes, but are always of comparatively short lengths seldom exceeding 15 or 20 feet. Common shapes are shown in Fig. 11. To obtain freedom from initial stresses due to unequal rates of cooling and from stresses due to

eccentricity with centrally applied loads, the shells of hollow cast-iron columns should be of uniform thickness throughout. This result may best be secured by pouring the column in an upright position; if cast in a horizontal position the core must be carefully restrained against flotation.

Timber columns should consist of single sticks and may be either circular or rectangular in cross-section. Two lengths are sometimes connected by means of cast-iron caps which also furnish seats for beams.

Concrete columns are made by pouring concrete into wooden or metal molds; they may be made of any desired shape or length. Such columns are generally reinforced by longitudinal steel rods extending from end to end of the column and held in place at intervals by transverse steel rings. The transverse reinforcement may be made to add materially to the strength of the column by placing the rings at frequent intervals or by making it in the form of a spiral extending from end to end of the column, the column then being called a hooped column. The strengthening effect of the transverse reinforcement is due to its influence in preventing the bursting tendency of the concrete when subjected to compression.

Splices. — Steel columns are commonly spliced by bringing the abutting ends into close contact after first planing them at right angles to the axis. Splice plates are used on webs and flanges to hold the sections in line. If the column carries no bending moment the size of splice plates and number of rivets may be determined by the designer's judgment; if the column carries flexure as well as direct stress the splice must be sufficient to transmit the flexure.

Changes of cross-sections in steel columns may be accomplished by changing the thickness of the material or by adding additional material. An advantageous location of a splice is at a section where the cross-section area is to be changed. If the column carries only direct compression and is loaded at intervals throughout its length such a section should be near the point of application of one of the loads and on that side of it in which the smaller stress occurs, e.g., in a high building column the section should be changed just *above* one of the floors. For columns carrying flexure as well as direct stress the splices should be located where the bending moment is small, as for example at a point of contraflexure. Cast-iron columns should

Fig. 10.

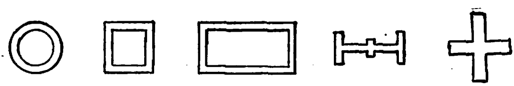

Fig. 11. Cross Sections of Typical Cast-iron Columns

not be used for positions where a considerable amount of flexure may occur or where they may be subjected to severe shock or vibration. Their use in construction is practically confined to buildings of moderate height. They may be spliced by bolting the flanges. In interior building columns the load is sometimes transferred from one section to another by means of a pintle extending between the beams which are supported on the cap of the lower column. Such a joint depends for its lateral rigidity upon the friction between the beams and column cap and can evidently transmit no bending moment.

Ratio of Unsupported Length of Column to Radius of Gyration. — The controlling factor in column formulas is the value of the ratio between the unsupported length of the column and the radius of gyration of its cross-section. If the column is of constant cross-section and restrained against lateral deflection at

both ends only, then l equals the total length of the column and r its least radius of gyration. If the column is held against lateral deflection in every direction at one or several intermediate points, the value of $\frac{l}{r}$ equals the largest value existing between any two adjoining lateral supports. If the column is held at an intermediate point in one direction only, the value of $\frac{l}{r}$ equals the maximum obtainable by using for l the length of either section, or the total length of the column, and for r in each case the corresponding least radius of gyration referred to any axis about which the column is free to bend. If the column is of variable cross-section the designer must use his judgment in determining the value of r to be used, but generally the value should be that at the middle of the unsupported length of the particular portion of the column that is under consideration.

Condition of Ends. — It was formerly assumed that the strength of columns used in practice depended very largely upon the condition of the ends. At the present time, however, no difference is made between round-ended, pin-ended and square-ended columns as used in ordinary practice. For columns of length such that Euler's formula should be applied, a distinction should be made between round-ended and square-ended columns (*see following section*). Columns with one free end should receive special consideration.

Recommended Formulas for Steel Columns.—

For Columns of Ordinary Length:

$$\frac{P}{A} = 16{,}000 - 70\frac{l}{r}, \tag{1}$$

l/r not to exceed 120 for principal members,
l/r not to exceed 150 for secondary members,
P/A not to exceed 14,000 lbs.

For meaning of symbols, see list following equation (4).

For Long Columns having values of l/r greater than allowed in formula (1), the column may fail by collapsing rather than crushing; in this case the following formulas should be used:

$$\text{Fixed Ends} \quad \frac{P}{A} = \frac{4\pi^2 E}{c}\left(\frac{r}{l}\right)^2, \tag{2}$$

$$\text{Round Ends} \quad \frac{P}{A} = \frac{\pi^2 E}{c}\left(\frac{r}{l}\right)^2, \tag{3}$$

$$\text{One Free End} \quad \frac{P}{A} = \frac{\pi^2 E}{4c}\left(\frac{r}{l}\right)^2, \tag{4}$$

where P = total allowable centrally applied load on column in pounds including proper allowance for impact,
A = minimum area of cross-section in square inches,
$\frac{l}{r}$ = maximum ratio of length to radius of gyration for any laterally unsupported section of column,
c = suitable factor of safety, usually 5 to 6,
E = modulus of elasticity in pounds per square inch.

Recommended Formulas for Cast-iron Columns. —

$$\frac{P}{A} = 6100 - 32\frac{l}{d}, \qquad \frac{l}{d} \text{ not to exceed } 40, \qquad (5)$$

where P = total allowable centrally applied load on column in pounds including proper allowance for impact,
A = minimum area of cross-section in square inches,
d = diameter of circular column or shorter side of rectangular column in inches.

Recommended Formulas for Timber Columns. —

For longleaf yellow pine, $$\frac{P}{A} = 1300\left(1 - \frac{l}{60\,d}\right), \qquad (6)$$

For shortleaf pine and spruce, $$\frac{P}{A} = 1100\left(1 - \frac{l}{60\,d}\right), \qquad (6a)$$

where P = total allowable centrally applied load on column in pounds (disregarding impact),
A = area of cross-section in square inches,
$\frac{l}{d}$ = unsupported length divided by least radius of gyration.

The values in (6) and (6a) are for railroad bridges. For highway bridges increase these values by 25 per cent. For buildings protected from the weather and reasonably free from impact, increase these values by 50 per cent. For other timbers, multiply value for longleaf yellow pine by ratio between working compressive stress of timber in question and of longleaf yellow pine. (*See also section on Unit Stresses in article on Timber.*)

Steel Column Details. — Columns composed of separate parts should be so constructed that the various parts will resist buckling as a unit; otherwise, the strength of the column will be no greater than that of the individual pieces combined. As an illustration of this, the column shown in Fig. 10 may be considered. If the two channels are not connected, the strength of this column will be only double that of the two separate channels, and the radius of gyration will have the low value corresponding to a single channel. Similarly a wooden column composed of thin planks bolted loosely together has little if any greater strength than the same number of separate planks standing alone. To fasten together the ribs of a steel column, plates or diaphragms may be used throughout its length, the plates forming a part of the main or stress bearing cross-section, or plates and lattice bars may be used as shown in Fig. 10. The width of the lattice bars is usually taken as the minimum value allowable for the rivets used. For columns consisting of two channels, the minimum sizes of lattice bars given in the accompanying table may be used. In no case should single lattice bars have a thickness less than 1/40 the distance between rivets connecting them to the channels; but for double lattice bars riveted at their intersection the thickness may be 1/60 of the distance.

Size of channel, in.	Lattice bar section, in.
8 and 9	2¼ by 5/16
10	2¼ by 5/16
12	2¼ by 5/16
15	2½ by 5/16

For columns of unusual size, the lattice bars should be carefully designed. (*See Spofford's Theory of Structures, N. Y., 1911, Art. 145.*)

Rivet Pitch in Built Steel Columns. — For columns carrying direct stress only, the rivets should not be farther apart than 6 inches or 16 times the thinnest plate connected and at each end or at each point of application of concentrated loads they should not be farther apart than four diameters of the

rivet. See also sections below on *Design of Tension Members* and *Design of Riveted Joints.*

Eccentrically Loaded Columns. — If the resultant force acting at any cross-section of a column is not applied at its center of gravity the column is said to be eccentrically loaded. The effect of an eccentric load is to subject the column to a combination of direct stress and flexure, and thereby to increase the maximum fiber stress over what it would otherwise be. A similar condition arises if the resultant force on the cross-section is the resultant of an axial force acting at the center of gravity of the section and a couple causing flexure at the section. The maximum fiber stress at such a section may be determined by the following closely approximate formula for the usual case where the resultant force acts in the plane of one of the principal axes and the neutral axis for flexure coincides with the other principal axis.

$$s = \frac{P}{A} + \frac{My}{I - \frac{Pl^2}{10E}}, \tag{7}$$

where s = maximum fiber stress at any section in pounds per square inch,
P = resultant axial force on section in pounds,
l = unsupported length of column in inches,
A = area of cross-section in square inches,
M = bending moment on section in inch-pounds,
I = moment of inertia of cross-section about neutral axis in (inches)^4,
E = modulus of elasticity in pounds = 29,000,000 for steel,
y = distance in inches from neutral axis to most remote fiber. (Neutral axis as used in this formula is the neutral axis for flexure.)

Flexure in a Building Column Carrying an Eccentric Load. — The case of a building column supporting a track for a traveling crane is a common one. The curve of moments for such a case is shown by the dashed line in Fig. 12 in which P is the applied load acting on the track at a distance x from the center of the column. The maximum bending moment always occurs at the load and depends upon the height of application of the latter. Its maximum value is Px and occurs when the load is at the top of the column.

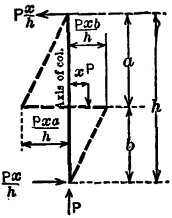

Fig. 12.

Proportions of Columns. —The following specifications should be closely followed:

In compression members the metal shall be concentrated as much as possible in webs and flanges. The thickness of each web shall be not less than one-thirtieth of the distance between its connections to the flanges. Cover plates shall have a thickness not less than one-fortieth of the distance between rivet lines.

The open sides of compression members shall be provided with lattice bars and shall have tie plates as near each end as practicable. Tie plates shall be provided at intermediate points where the lattice is interrupted. In main members the end tie plates shall have a length not less than the distance between the lines of rivets connecting them to the flanges, and intermediate ones not less than one-half this distance. Their thickness shall not be less than one-fiftieth of the same distance.

Abutting joints in compression members when faced for bearing shall be spliced on four sides sufficiently to hold the connecting members accurately in place. All other joints in riveted work, whether in tension or compression, shall be fully spliced.

Where splice plates are not in direct contact with the parts which they con-

nect, rivets shall be used on each side of the joint in excess of the number theoretically required to the extent of one-third of the number for each intervening plate.

Column Caps, Bases and Brackets. — The proper application of the applied loads to the column, and the distribution of the column load over the footing, is a matter of great importance. The three following rules should be applied in designing column caps:

a. Provide sufficient bearing area so that the crushing strength of the column, or of the loading beam, girder or column will not be exceeded.

b. Arrange connections to eliminate eccentric application of the load, or if this is impossible to reduce the eccentricity to the smallest possible amount.

c. Arrange connections so that the stress-bearing portions of the column shall be directly under the stress-transmitting portion of the loading member, e.g., if a column receives load from a girder, the outstanding legs of the end-stiffeners on the girder should be located directly over the webs of the columns.

Typical column bases are shown in Fig. 13. The same general rules should be observed in the design of column bases as in the design of column caps. The advantage of a separate base is that it can be set up on the foundation and leveled to receive the column with less difficulty than would be the case with the finished column. Such bases should always be planed on top and the base of the column should also be planed. Steel columns to which cap and base plates are shop riveted should be planed at each end before these plates are riveted on, and the cap and base plates are also generally planed on top and bottom respectively.

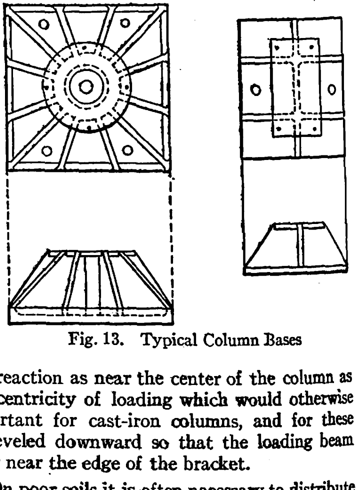

Fig. 13. Typical Column Bases

It is important that brackets for connections of girders to columns should always be designed so as to throw the resultant beam reaction as near the center of the column as possible in order to reduce the eccentricity of loading which would otherwise occur. This is particularly important for cast-iron columns, and for these the brackets should be slightly beveled downward so that the loading beam or girder cannot be supported at or near the edge of the bracket.

I-Beam Column Footings. — On poor soils it is often necessary to distribute heavy column loads over an area so large as to require a special footing which may be economically constructed of steel beams, in concrete. The beams should not be closer together than 3 inches to permit concrete to be easily placed between and around them. The method of design of an I-beam footing for the ordinary case, that of a column carrying direct load only, is as follows: (1) Determine the number of square feet required in the footing; (2) assume the number of tiers of I-beams; (3) assume the entire load above any given layer of beams (weight of over-lying footing courses and column load) to be distributed equally over all the beams in that layer and assume that each beam is uniformly loaded; (4) determine the maximum moment on the beam, which will occur at the center and equal approximately

$$M = \frac{W}{8n}(l - l_1) \tag{8}$$

where W = load on layer of beams under consideration, n = number of beams, h = portion of beam loaded from above, in feet, and l = length of beam loaded from below, in feet; (5) determine in the usual manner the size of beam required to carry this bending moment; (6) test the web thicknesses of the beams selected to see if they are sufficient to transmit the applied load without buckling, applying formula (1).

Pile Footings. — If the ground is soft, piles may be necessary to provide sufficient bearing area. For the allowable bearing value for these see Baker's *A Treatise on Masonry Construction*, N. Y., 1909.

Cost of Columns and Footings. — Steel columns cost about the same as steel girders, values for which are given in the section on *Cost of Girders*, above. In determining the weight of columns it should be remembered that the details will add materially to the weight of the stress-bearing section, especially in the case of latticed columns, where the excess may amount to as much as 50 per cent. For the cost of footings, the I-beams may be computed on a pound price basis from the weekly quotations given in *The Iron Age* with a reasonable allowance for transportation and delivery, or more accurate figures can be obtained from a local dealer. For cost of cast-iron columns see section on *Cost* in article on *Iron, Pig and Cast*. For the cost of concrete and excavation, see articles on these respective subjects.

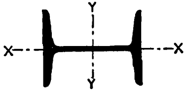
Tables for Steel Columns. — The allowable load for a number of simple steel columns and the important properties of the columns are given in Tables VII to X. To determine the allowable load for built-up columns not given in the table the radius of gyration may be interpolated for columns having the same general dimensions and the unit stress computed by substitution in the column formula. The areas and other properties of the simple structural shapes, such as beams, angle irons, and channels, are given in Tables II to VI above.

These tables are all based on the formula

$$\frac{P}{A} = 16{,}000 - 70\frac{l}{\rho}$$

with a maximum value of 14,000 and are calculated for Cambria Steel Co.'s sections. The load is assumed to be applied at the center of gravity of the column and to act parallel to its axis.

TABLE VII.—STEEL I-BEAM COLUMNS



ρ_x = radius of gyration about axis X-X
ρ_y = " " " " " Y-Y

Depth of beam, in.	Width of flange, in.	Weight per foot, lb.	Thickness of web, in.	Area of column, sq. in.	Least radius of gyration ρ_x, in.	ρ_y, in.	Max. allowable load P in thousands of pounds for various values of $l \div \rho$. To determine strength of column use maximum possible value of $l \div \rho$. If column is unsupported laterally use for ρ the value ρ_x.

TRUSSES, DESIGN OF. — All trusses may be divided into two general classes based upon the methods necessary to determine the bar stresses; if these stresses can be determined by the application of the three equations of equilibrium (*see paragraph on Equations of Equilibrium, above*), they are statically determined; otherwise they are statically undetermined. It should be noted that a truss may be statically undetermined with respect to the outer forces, i.e., the reactions cannot be determined by statics; or it may be statically undetermined with respect to the inner forces, i.e., the bar stresses cannot be determined by statics.

Trusses that are statically indeterminate through having superfluous bars or reactions are frequently constructed because of their supposed rigidity and economy, but it is doubtful if such trusses are desirable.

Statically determined trusses may be distinguished from statically undetermined trusses by comparing the number of unknown reaction components plus

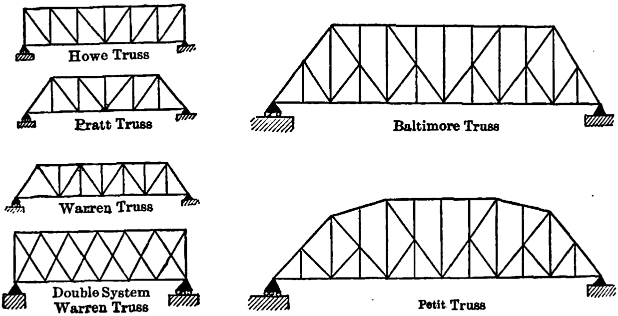

Fig. 14. Bridge Trusses

the number of bars with the number of joints. In general it may be stated that any planar truss supported at two points will be statically determined provided the number of bars equals $(2n-3)$, where n is the number of joints. If the number of unknown bars and reaction components combined exceed twice the number of joints the truss is statically indeterminate but may usually be computed by methods based upon its elasticity. If the number of unknowns is less than twice the number of joints the truss is unstable and may collapse; such structures should never be constructed.

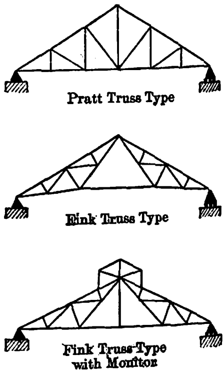

Fig. 15. Roof Trusses

The preceding test should not be used alone to determine whether a truss is or is not stable. The framework should also be so put together as to make it consist of a series of triangles.

Common Types. — All the trusses shown in Figs. 14 and 15, except the double-system Warren truss and the roof truss with monitor, are statically determined; the former may be made statically determined by omitting one of the bars, say a diagonal; the latter by omitting one properly chosen bar.

Theory of Trusses. — The common theory of trusses is based upon the following assumption:

That the members are connected at the intersections of their center of gravity lines by frictionless pins, and that in consequence the stresses in the various members are all direct stresses. The assumption of frictionless pins is approximate particularly in the case of riveted trusses; however, the results obtained by this method are sufficiently accurate for trusses of ordinary proportions and are in common use. Great care should be used in design to insure that center of gravity lines meet at the joints, otherwise the connection will be eccentric and the truss exposed to bending as well as direct stress.

The methods of computing stresses in ordinary trusses involve only the correct application of the three equations of statics (*see section on Equations of Equilibrium, above*). Three methods are in common use: viz., method of joints, method of moments, and method of shear. All of these are methods of sections and are applied by passing a section through the bar under consideration, cutting the truss apart and applying the equations of equilibrium to the outer forces on one of these sections and the stress in the bar under consideration. The first two of these methods are described below.

Method of Joints. — The method of joints is the most general of the three methods of computing the stresses in trusses; it may be applied either analytically or graphically.

Analytical Method. — The mode of procedure for this method is as follows: (1) Computation of reactions. (2) Selection of a joint at which only two bars meet. (3) Application of the two equations of equilibrium, $\Sigma H = O$ and $\Sigma V = O$, to the outer forces and unknown bar stresses acting at this point. The bar stresses should be assumed as tension, that is, as acting away from the joint; a negative result in any case would indicate compression. (4) Consideration of any other joint at which only two unknown bars meet and determination of the stresses in these bars in the same manner, treating known bar stresses as outer forces.

Graphical Method. — This method consists of drawing polygons of forces for each joint in succession. It may be employed readily by draftsmen and others who are not familiar with truss theories. It is also self-checking and reasonably rapid. It is less accurate than the analytical method, but if the diagrams are carefully constructed it is accurate enough for ordinary structures.

The mode of procedure is: (1) A sketch of the structure is drawn to any suitable scale and on it are shown all the outer forces including reactions. (2) All the forces and bars are designated by letters so located that each force and each bar will lie between two letters and only two, as illustrated by Fig. 16. (3) A polygon of outer forces is drawn. This should be drawn to a scale of sufficient size to give the desired accuracy. The forces should be plotted in the order in which they are reached by going around the figure in a clockwise direction, and should be lettered at the ends by the letters in the order obtained by this clockwise rotation. This polygon should close if the reactions have been determined

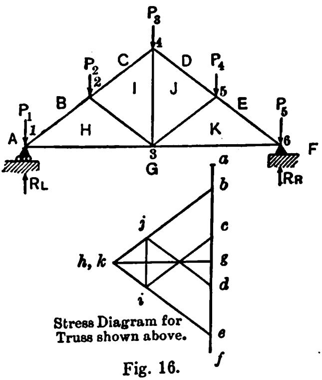

Fig. 16.

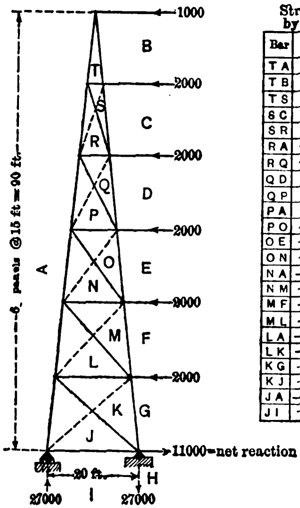
correctly. (4) A triangle of forces for each joint is drawn, beginning at any joint where an outer force and two bars only meet, and proceeding thence, joint by joint, selecting the joints in such an order that at no joint will there be more than two undetermined forces to consider. The sides of these triangles representing the outer forces are the sides of the force polygon. The sides representing bar stresses should be lettered at the ends by the letters obtained by going around the joints in a clockwise direction. The diagram thus drawn should form a closed figure. (5) The magnitude and character of the bar stresses are determined from the diagram. The magnitude of the stress in any member equals the length of the line of the diagram parallel to the bar in question measured to the scale of the force polygon; its character is determined by the order in which the letters are reached in going about any joint in a clockwise direction. For example, to determine the character of the stress in bar *CI* of Fig. 16, note that *ci* in the stress diagram acts downward to the left, as determined by the order in which the letters are reached in going around joint 2; hence the stress in *CI* also acts downward to the left, or toward the joint, since the bar is above the joint, and is therefore compression. A similar result is obtained by considering joint 4. For this joint clockwise reading gives the designation of the bar as *IC*, and *ic* in the stress diagram acts upward to the right, that is toward joint 4, since the bar is below this joint.

Solutions by Graphical Method. — Fig. 16 shows a small truss drawn to scale and with all the outer forces represented in direction and point of application. The force polygon is *abcdefga;* this is a straight line, since all the forces are vertical. In it $ab = P_1$, $bc = P_2$, etc. The reactions R_L and R_R are represented by *ga* and *fg*. The triangle of forces for joint 1 is *gabhg* (*gb* is the resultant of R_L and P_1). Reading around joint 1 in a clockwise direction shows that the magnitude and direction of the stress in bar *BH* is determined by the length and direction of *bh* in the force polygon; as this acts downward to the left, it acts toward joint 1 and hence is compression. In the same manner the stress in *HG* is found to be tension. The stresses in the other bars may be determined similarly.

Fig. 17 shows a simple tower with wind forces acting on one side only. Ordinarily the wind forces on a tower would be equally divided between the two sides but they are all taken on one side here in order to more clearly illustrate the method. The only difference in the result would occur in the stresses in the horizontal members. In this case the diagonals in all panels are assumed to be tension members, only one of which in any one panel is in action under the forces shown. Inspection shows that in each case the bar shown dotted should be considered as out of action. The stress diagram and the scaled values of stresses in the bars are also shown in the figure.

Method of Moments. — This method of finding truss stresses is based upon the application of the equation $\Sigma M = 0$. It is very useful for determining stresses in individual bars of many trusses, but is not so general as the method of joints and is frequently inapplicable to some bars even in the simplest trusses. Like the method of joints, it is also a method of sections, the truss being considered as divided into two portions and the equilibrium of one of these portions under the influence of the outer forces and the stress in the cut bar being considered. The method can be used to determine the stress in a given bar when all the other bars cut by the section, or their prolongations, meet at a point not on the line of action of the given bar. This point should be selected as the origin of moments.

Design of Tension Members. — The design of tension members involves little more than the selection of bars with sufficient net area to carry the total stress without exceeding the allowable unit stress. Steel or iron tension



Stresses by scale

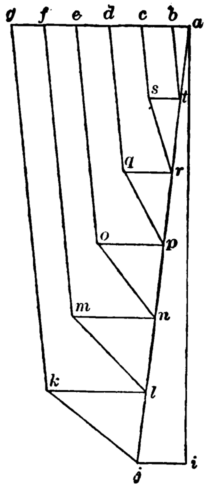

Fig. 17.

members may be divided into two general types: viz., solid bars rectangular or circular in cross-section, and built-up members composed of structural shapes riveted together. Solid bars are used generally in pin trusses for diagonals and bottom chord members, and in Howe trusses for verticals. Built-up members are generally employed for tension members in riveted trusses and for the end hangers in pin-trusses.

Solid Tension Pieces. — The eye bar shown in Fig. 18 is commonly used for the solid bar type of tension members. Such bars are made by most of the large steel manufacturers and are fully described in their handbooks. The heads of these bars are designed so that the bar if tested to destruction will fail in the body rather than in the head, and the engineer should specify that full-sized tests should give this result and not attempt to proportion the heads. A good rule to observe in selecting bars is to keep the thickness between

Fig. 18.

Fig. 19.

one-sixth and one-third the width. Eye-bars are generally used in pairs, since an odd number of bars would give a poor arrangement on the pin. For counters adjustable eye-bars, such as those shown in Fig. 19, may be used, the two parts being connected by a turnbuckle or sleeve nut; iron rods with loops formed by welding may be used if the stresses are small. In proportioning adjustable members allowance must be made for the decrease in section due to the screw threads. It is usually advisable to upset the screw end, so as to give sufficient area at the root of the thread to make the bar as strong there as elsewhere. For short rods, however, the labor cost involved in this process may be greater than the saving of material would warrant.

Riveted Tension Bars may be made of various sections such as channels, plates and angles, etc. Although these members do not need latticing or tie-plates to keep the separate parts from buckling, as in the case of columns, some connection between them should be used to make the different parts act together. The design of these details must be left to the judgment of the engineer.

Design of Riveted Joints.— A riveted connection may fail in one of the following ways: (*a*) by the shearing of the rivets, (*b*) by the crushing of the rivets or of one of the pieces upon which they bear, (*c*) by the tearing of the rivets through one of the connected pieces.

Shearing Strength of Rivet. — Under (*a*) it should be noted that the allowable shearing value of the rivet may be found by multiplying its cross-section area by the allowable shearing stress per square inch, and that the area of a ⅞-inch rivet is 0.60 square inch, and of a ¾-inch rivet 0.44 square inch. In designing rivets to resist shear the plane upon which the maximum shear occurs must always be determined. If the maximum shear be equally distributed over two planes the rivet is said to be in *double shear.*

Bearing Strength of Rivet. — The permissible bearing, or crushing strength of a rivet against a given plate is determined by multiplying the allowable bearing strength per square inch by the diameter of the rivet and the thickness of the plate in question.

Distance of Rivet from Edge of Member. — To prevent the failure noted under (*c*) the following empirical rule may be used: rivets may not be spaced closer than three times the diameter, and the distance of a rivet from the edge or end of a piece may not be less than 1¼ inches for a ⅞-inch rivet if the edge in question be rolled or planed, or 1½ inches if it be sheared, though where possible this distance should be at least twice the diameter of the rivet. For other sizes of rivets proportional allowances should be made. These values refer to the center of the rivet in each case.

Riveted Joints Carrying Torsion. — For cases where torsion as well as direct stress has to be transferred by rivets, as is sometimes the case where brackets carrying cranes are riveted to the sides of columns or where girders are riveted to columns, the conditions shown by Figs. 20 and 21 may occur. For the case shown in Fig. 20 the rivets carry torsion only, and each rivet may be assumed to offer a resistance to torsion proportional to its distance from the center of gravity of the group. The resistance to torsion of such a group is

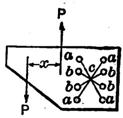

Fig. 20.

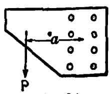

Fig. 21.

$$R = \frac{rI}{d},$$

where r = the allowable working value of the most stressed rivet in pounds,
I = summation of the squares of the distances in inches from the center of gravity of the group of rivets to each rivet,
d = distance in inches from center of gravity of group of rivets to the most stressed rivet,
R = resistance to torsion of the group of rivets in pounds.

In applying the formula to the case shown in Fig. 20 $d = ac$ and the stress in the rivets at a is r. For the case shown in Fig. 21 this method must be modified to allow for the effect of the vertical load. To make this correction it is only necessary to determine the allowable resistance to torsion consistent with the rivet also carrying its share of the vertical load.

CONTINUOUS GIRDERS, BEAMS, SLABS AND TRUSSES. — These are structures which are continuous over several points of support. They are statically indeterminate (*see section on Trusses, above*) with respect to the outer forces and hence the moments and shears should be determined by the "three moment equation" (*see above*). Continuous girders are commonly used in reinforced concrete construction, in which case the continuity is allowed for by the following simple rules recommended by the Joint Committee on Concrete and Reinforced Concrete. (*See article on Concrete.*)

(*a*) "That for floor slabs the bending moments at center and at support be taken as $\frac{wl^2}{12}$ for both dead and live loads, where w represents the load per linear foot and l the span length.

(*b*) "That for beams the bending moment at center and at supports for interior spans be taken as $\frac{wl^2}{12}$, and for end spans as $\frac{wl^2}{10}$ at center and at adjoining support, for both dead and live loads.

(*c*) "In the case of beams and slabs continuous for two spans only, the bending moment at the central support should be taken as $\frac{wl^2}{8}$ and near the middle of the span as $\frac{wl^2}{10}$.

(*d*) "At the ends of continuous beams the amount of negative moment which will be developed will depend on the condition of restraint or fixedness, and this will depend on the form of construction used. There will usually be some restraint, and there is likely to be considerable. Provision should be made for the negative bending moment, but, as its amount will depend on the form of construction, the coefficient cannot be specified here, and must be left to the judgment of the designer."

SUBSTATIONS, LIGHTING. — (*See also Batteries, Storage, Applications of; Bus-bars and Bus-bar Structures; Circuit Breakers; Converters, Synchronous; Distribution Lines; Distribution Systems; Lighting Plants; Motor-Generators; Regulators; Relays; Substations, Railway; Switchboards; Switchgear Equipment for Power Stations; Transformers.*) Three types of substations are employed in lighting systems viz.:

Substations for Voltage Conversion and Regulation on A-C. Systems. — These substations receive power from high-tension transmission lines or primary feeders designed for economical cross section of conductor rather than for small voltage drop. The standard equipment of such substations includes bus-bars and oil circuit breakers for high-tension lines, step-down transformers, bus-bars, oil switches and voltage regulators for delivery lines, and often in addition constant-current transformers serving local series street-lighting circuits. The construction of bus-bar and switch structures is similar to that in power stations for the control of circuits of equal power. Transformers are often of the air-blast type, and are usually grouped in banks of three single-phase units. The constant-current transformers supplying d-c. arc circuits are associated with mercury-arc rectifiers. The equipment is usually arranged to make the current path through the substation as short and direct as possible. Each outgoing line has its individual equipment of voltage regulators in the best practice.

Substations for the Conversion of Frequency. — Such substations are usually combined with the conversion of voltage. These substations receive power from 3-phase, 25-cycle primary feeders, convert it to 60 cycles and transform its voltage for the supply of local 60-cycle lighting feeders. The type of frequency-changer most used is a pair of synchronous machines of the proper frequency ratio running on a common shaft. When space is restricted the vertical-shaft type is generally used. By proper regulation of the field excitation of the motor element it is possible to control the power factor and terminal voltage of the primary feeders to the most advantageous values.

Substations for the Conversion of Alternating Current to Direct Current. — The alternating current is received from high-tension, 3-phase, primary feeders, and is converted to low-voltage direct current for the supply of local d-c. lighting circuits. Substations of this type are largely used in connection with the 3-wire lighting networks in large cities. The standard equipment comprises bus-bars and oil switches for incoming lines, either (1) synchronous converters associated with lowering transformers and voltage regulating accessories, or (2) motor-generators, and direct-current switchboard equipment. In very many cases the above equipment is supplemented by a large floating storage battery to insure the continuity of service in case of breakdowns. A converter must be associated with step-down transformers while the motor element of the motor-generator may be wound for voltages up to 20,000. The converter equipment is somewhat more efficient and in most cases slightly less expensive. The motor-generator equipment affords the greater range of power-factor compensation.

For methods of voltage control see *Converters, Synchronous.*

In converter substations the step-down transformers are usually in banks of three single-phase units. Transformer banks supply converters individually and are not connected in parallel on the low-tension side. Converters of 300 kw. and higher are usually wound 6-phase. The neutral point of a well balanced 3-wire system may be derived from the neutral of the transformer bank. For storage battery arrangements see *Batteries, Storage, Applications of.*

BIBLIOGRAPHY. — See articles on *Power Stations.*

[W. E. Wickenden.]

SUBSTATIONS, RAILWAY. — (*See also Converters, Synchronous; Railways, Energy Requirements for; Switchboards; Switchgear Equipment; Transformers.*) Substations are used for electric railways when the length of the road is so great that the whole road cannot be supplied with one power station at the voltage required by the motors without either an excessive drop in voltage or a prohibitive amount of copper or both. Practically all electric railways have developed to such an extent that substations are required for successful operation.

ECONOMIC CONSIDERATIONS. — The location, capacity and number of substations is a matter for careful study and calculation, involving not only the cost of the copper required for distribution and the cost of the substations, but also the distribution of traffic and special local conditions. The fundamental economics of the subject are expressed by the general theorem that the cost of operating the substations plus the cost of interest and fixed charges on investment in substations and line copper shall be a minimum. This is explained by the fact that if to any given arrangement an additional substation be added with the proper rearrangement of the spacing, the amount of copper used in the distributing system may be considerably decreased on account of the lesser distance between substations. If the saving in interest on the value of the copper is greater than the cost of operation of this new substation plus the interest and fixed charges on the first cost of the substation, the change is warranted.

Allowable Voltage Drop. — The distance between substations depends directly upon the allowable loss in voltage, the amount of copper in the trolley and inversely as the load. The allowable loss in voltage is a matter of the special conditions of each road. However, roads may be divided into two classes and the allowable drop in voltage for average and maximum load conditions specified, as in the accompanying table.

Service	Average load	Maximum load
	Per cent	Per cent
City	8	15
Interurban	12	30

The two conditions which determine the allowable drop in voltage are the effect on the lights and the effect on the control circuit of the car, each of which factors requires a lesser drop in voltage than the actual operating characteristics of the motors.

Distance between Substations. — For the service usually found in practice the following tabulation shows the average or customary distance between substations.

Where the length of track receives its power from only one direction the allowable distance for a given drop in voltage is one-quarter the distance allowable between substations.

Capacity Required. — The capacity of the substation depends upon the traffic and the size of the cars, since if there are many cars operating it is probable that only a few will be starting simultaneously and it is during starting that the cars demand the maximum amount of power. It is, therefore, necessary to determine the number of cars which will be located on the section of

Volts	Type	Miles between substations	
		Single-track road	Double-track road
600	Direct-current, Trolley	10	10
600	Direct-current, 3d Rail	13	19
3,300	Single-phase, Trolley	17	23
1,200	Direct-current, Trolley	19	25
1,200	Direct-current, 3d Rail	38	43
6,600	Single-phase, Trolley	45	50
11,000	Single-phase, Trolley	..	70

track supplied by one substation and the frequency of starting. In interurban service the number of cars on a given section is given by the formula:

$$X = \frac{2 \times (\text{length of section}) \times (\text{number of cars per hour})}{\text{schedule speed in miles per hour}}.$$

The average load on the substation is equal to the average power demand of each car times the number of cars on the section divided by the efficiency of the distribution system. In a complex system the local conditions must be studied to determine how many of these cars are liable to be starting at once. In other than city roads a load factor of from 0.3 to 0.5 may be used to determine the maximum load on a substation, and in single-track interurban roads it is customary to assume one car starting and one car running. See article on *Railways, Energy Requirements for.*

TYPES OF SUBSTATIONS. — In practice there are two types of substations: 1. for transforming from alternating to direct current, and 2. for transforming from high-voltage alternating current to low-voltage alternating current.

In standard direct-current railways it is customary to generate power in the power stations at about 2200-volt three-phase alternating current, step up by means of transformers to 33,000 volts 3-phase, transmit over any distance to the substations at this voltage, transform from 33,000 volts to approximately 400 volts 3 phase and then to convert to direct current at 600 volts in which form the power is used by the motors of the cars. This is the standard a-c.-d-c. substation. In certain single-phase a-c. railways it is found necessary to transmit the power over long distances at a higher voltage than can be collected from the trolley, in which case the a-c.-a-c. transformer substations are installed to convert the alternating current at the high transmission voltage to alternating current at a voltage convenient for the trolley and collector devices.

SUBSTATIONS FOR TRANSFORMING FROM ALTERNATING TO DIRECT CURRENT. — In these stations it is almost universally the custom to employ synchronous converters to convert from a-c. to d-c., rather than motor-generator sets, as the converters have a higher efficiency and may be compounded to give the desired regulation. Thus the converter makes possible a saving in first cost, space and energy as compared to the motor-generator set. A standard a-c.-d-c. railway substation usually contains the

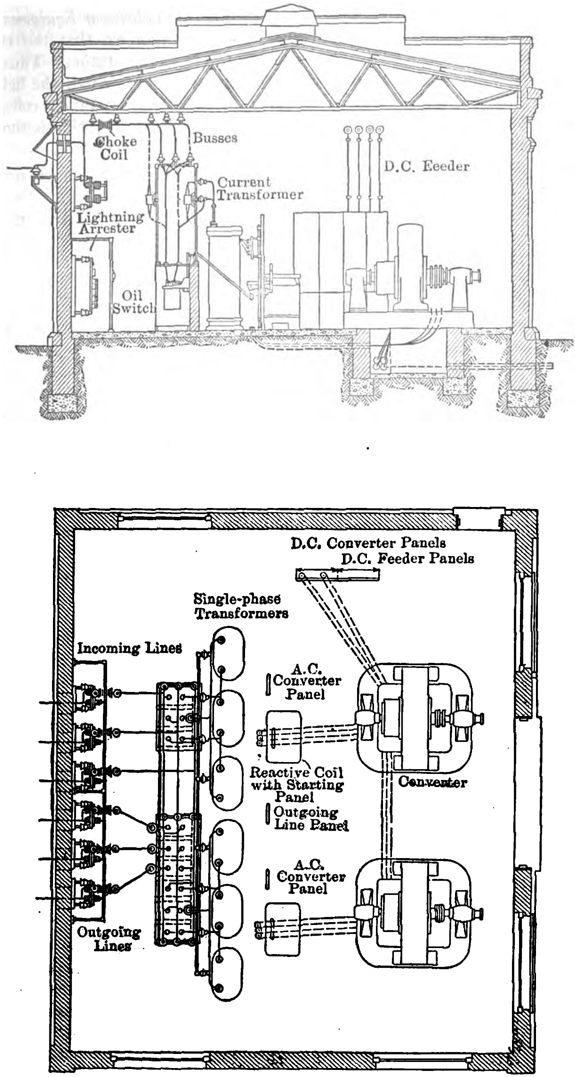

Fig. 1. Plan and Elevation of Typical Railway A-C.-D-C. Substation

following pieces of apparatus: converters, transformers, reactances, blowers, cables, switchboard.

Arrangement of Apparatus.—(*See also article on Switchgear Equipment.*) It is customary to arrange the apparatus in a substation so that the current travels in as nearly as possible a straight line across the station. Thus, with the incoming line on one side there are in the order mentioned: the lightning arresters, oil switches, transformers, a-c. switchboard, reactance coils, converters, d-c. line panel. A typical arrangement for a small station is shown in Fig. 1; see also Fig. 16 in article on *Switchgear Equipment*.

Floor Space Required.—For substations with all apparatus on one level the floor space required is about 0.20 square feet per kilowatt. In cities where real estate is expensive, it may be desirable to put the oil switches and lightning arresters in a gallery on the upper level and the transformers on a floor above, but this involves more expense for attendance.

Standard Voltages and Frequencies.—The following three-phase voltages have been standardized for railway work: 11,000 volts with transformers delta connected on the high-tension side; 33,000 volts with transformers *Y* connected; 66,000 volts with transformers *Y* connected. A frequency of 25 cycles per second is employed in almost all railway installations, as converters are more reliable at this frequency. Certain stations which are obliged to take power from previously existing power stations use a frequency of 60 cycles.

Converters.—(*See article on Converters, Synchronous, for data regarding converters.*) Compound-wound converters are used where the load is variable in order to maintain a constant voltage at the direct-current terminals of the converter irrespective of load. The converter by means of its series winding is made to take a leading current which, in passing through the reactance of the line, the transformers or through an additional reactance introduced for the purpose, tends to neutralize the line drop. (*See Transmission Lines.*) In city service where a large number of cars are operating on one section, the load is fairly constant and shunt-wound converters are generally used.

Both 3-phase and 6-phase converters are universally used, the 3-phase for the smaller capacities and the 6-phase converters for the larger capacities. In a 3-phase converter for a direct e.m.f. voltage of 600 at no load, the transformers should supply the converter with 370 volts between rings or between lines. In the 6-phase converter it is customary to use the diametrical connection, in which each transformer secondary supplies 430 volts to the converter, giving 600 volts at the commutator. Each converter for railway work is customarily supplied with a "speed-limiting" device on one end of the shaft and an "end-play" device on the other end. (*See Converters, Synchronous.*)

Methods of Starting Converters.—(*See also below under Operation.*) There are several methods of starting rotary converters, as is explained under *Converters, Synchronous*. Starting from the alternating-current end as an induction motor is most desirable for railway work, as it avoids the necessity of synchronizing and requires less time. The ability to start a machine quickly and get it on the line in the shortest possible time is very important in railway work, and is an advantage inherent in this method of starting. Three-phase converters are started, by means of suitable starting switches, from one-half voltage taps on the transformer secondaries and take approximately full-load current from the line. Six-phase converters are started from $\frac{1}{3}$ voltage taps and take $\frac{3}{4}$ full-load line current. Since 60-cycle converters usually take a greater starting current than 25-cycle converters and are usually operated on a system supplying power for other purposes, where voltage disturbances are objectionable, special means of starting 60-cycle converters are frequently employed.

Transformers. — (*See article on Transformers.*) The transformers used in railway substations may be either of the oil-cooled, air-blast or water-cooled type. The oil-cooled type is used where the units are small in capacity, i.e., less than 400 kilowatts, and where the expense of the complications for air blast or water cooling are not warranted. Air-blast transformers are used in all except the smallest sizes, and for voltages up to and including 33,000; the objections to their use are the necessity of providing a pit, air ducts and blower to supply the ventilation. Water-cooled transformers (which are oil-insulated transformers with water circulating in a special coil submerged in the oil) are built in sizes from 500 kilowatts upwards and for all voltages. Their use depends upon the availability of water for cooling purposes. The usual aggregate capacity of transformers for the various sizes of synchronous converters is about the same as the converter capacity.

Transformer Connections. — The transformers may be either of the single-phase or three-phase type. For small or moderate installations the single-phase type is preferable on account of the economy of maintaining only one single-phase transformer as a spare for a whole station. In railway work it is customary to connect the secondary of the transformers in delta for three-phase, because of the possibility of operating at reduced output on open delta in case of failure of one transformer. The primary windings of the transformer are usually connected *Y* with grounded neutral. It is common practice to provide transformers for railway work with four 2½ per cent taps on the high-potential winding, in order to use similar transformers in all substations and yet make allowances for the difference in the line drop between the power station and the various substations. Either ⅓- or ½-voltage taps are provided on the low-potential side for starting the converters.

Blowers for Air-blast Transformers (*see Blowers and Compressors*) are usually driven by 25-cycle 3-phase induction motors receiving power from the low-tension side of the transformers. The amount of air required per minute per kilowatt rating of each transformer ranges from 3 cubic feet in the large sizes to 5 cubic feet in the small sizes. This air is supplied at a pressure of from ⅜ to 1 ounce per square inch. The blowers must be capable of supplying this amount of air with an allowance of about 10 per cent for leakage in the air-blast chamber. It is customary to provide two blower sets each capable of supplying air for all the transformers in the station and maintaining one as a reserve unit. In a very large station 3 blower sets are sometimes provided, two of which are together capable of supplying the service and the third is a reserve. A rough idea of the size of the motor necessary to drive a blower for a given purpose may be obtained from the following formula:

$$\text{Horse-power} = \frac{(\text{cu. ft. air per minute}) \times (\text{pressure in ounces})}{1200}.$$

Air Duct for Air-blast Transformers. — The pit or trench over which air-blast transformers are placed must be made water-tight and well drained, as any moisture accumulating is liable to be carried into the transformers where it will injure the insulation.

Voltage Regulation. — Use of Reactances. — The voltage at the d-c. bus-bars is kept constant irrespective of load by means of line compounding, which consists in adjusting the shunt-field excitation of each converter so that the converter takes lagging current at no load, operates at unity power factor at about ¾ load and takes leading current at all loads greater than ¾ load. To accomplish this compounding, it is necessary that there should be a certain amount of reactance between the power-station bus-bars and the converters. (*See Converters, Synchronous.*) There is seldom enough reactance in the trans-

mission line for this purpose, so that additional reactance is inserted either by the use of special transformers having considerable leakage reactance, or by means of reactance coils. The usual reactance coil has a capacity in kv-a. equal to 15 per cent of the kilowatt rating of the converter, i.e. with full-load current passing through the reactance the voltage measured across its terminals would be 15 per cent of the voltage to neutral on the a-c. side of the converter.

Reactance coils are either oil cooled or air blast depending upon the transformers used and are usually built with the three circuits in one unit, with the starting switches for the converters mounted upon the frame. For 6-phase converters a 3-phase reactance coil is used, but since the current per wire is one-half that of the current of a 3-phase converter of the same rating, the reactance per line must be twice as great for the 6-phase converter.

Switchboards. — *(See also article on Switchboards.)* The following sections of switchboards are standard for converter substations.

1. Incoming a-c. line panel.
2. Outgoing a-c. line panel.
3. High-tension a-c. converter panel.
4. D-c. converter panel.
5. D-c. feeder panel.
6. Equalizer and negative panel (on the converter).

Where a substation is tapped off a transmission line at an intermediate point it is good practice to bring the transmission line into the substation, interpose control switches, and then carry the circuit out of the substation on to the next substation. For this reason, in all but terminal substations, it is customary to provide both an incoming and an outgoing a-c. line panel. In connection with the a-c. panel of the switchboard there are a line switch, lightning arrester, choke coil, current transformers and main oil switch, by means of which potential may be removed from all transformers. Between the transformers and the converter are the starting switches, reactance coil and possibly measuring devices.

Direct-current Panels. — Single-pole switchboard panels are used, the positive main bus-bar being the only one on the board. The negative terminals of the converters are connected with switches to the negative or ground return bus-bar, which is frequently located beneath the converter. The series field is connected on the negative side, and the equalizer, series-field-shunt and field break-up switches are frequently placed on the machine itself. The equipment of a standard d-c. converter panel comprises one of each of the following:

Carbon break circuit breaker with overload and low-voltage release, the latter interconnected to the speed-limit device.
Illuminated dial ammeter with shunt.
Field rheostat.
Two-point receptacle.
Single-pole main switch.
Single-pole double-throw station lighting switch.
Watt-hour meter.

Storage Battery. — In certain installations, where reliability of service is of utmost importance, a storage battery is installed, operating in parallel with the converters, and preferably regulated by a series booster. Such a storage battery will not only take care of the load for a considerable period of time in case either the transmission line or converters are out of action, but it will also improve the load factor of the system and thereby the line regulation. In

other cases, where the service does not warrant the outlay for such a storage-battery system, a small storage battery is sometimes installed to take care of the lighting of the substation in case the converters should shut down accidentally. See articles on *Batteries, Storage*.

Ventilation. — As the transformers, reactance coils and converters all dissipate a considerable amount of energy in the form of heat, a substation must be well ventilated in order that the temperature of the air surrounding the apparatus is not so great as to cause an injurious temperature in the apparatus itself. This is particularly important where oil-cooled transformers are used.

Crane. — Where ground space is limited it is good economy to provide a crane in order that the various pieces of apparatus may be lifted over each other when they are taken apart for repairs, as otherwise considerable space must be left to move them about to and from the entrance. See article on *Cranes*.

Operation of Converter Substations. — The only apparatus in a converter substation that requires any great amount of attention are the synchronous converters. As noted above these are usually started from the a-c. supply.

Instructions for Starting a Synchronous Converter from A-C. Supply. —

1. Open all switches except main negative (on machine).
2. Close a-c. line switch feeding busses.
3. Close H.T. transformer switch.
4. Close starting switch on low-voltage taps.
5. When converter reaches synchronism as shown by low frequency of swings of d-c. voltmeter, close equalizer switch.
6. Close switch between series field and the shunt to series field.
7. Correct polarity if necessary by throwing shunt-field break-up switch to reverse position, leaving it closed only momentarily, then throw to running position.
8. Connect a-c. terminals of converter to full voltage of transformers by throwing starting switch to running position.
9. Close d-c. circuit breaker.
10. Adjust field rheostat.
11. Close main d-c. switch.
12. Adjust for correct division of load, power factor and voltage.

Load Factor and Efficiency. — The load factor (q.v.) of a converter substation is usually low, from 30 per cent to 50 per cent, i.e., the load on the station is relatively light except during the morning and afternoon rush-hours, 7 to 9 A.M., and 5 to 7 P.M respectively (*see Train Dynamics*). The all-day efficiency of the station itself, or the ratio of the kilowatt-hours output to the kilowatt-hours input, is less than the efficiency at maximum or rated load; but the over-all efficiency between the a-c. generators in the power house and the cars is about constant throughout the day, since the efficiency of a transmission line increases with decrease of load, thus offsetting the low light-load efficiencies of the transformers and converters. In general practice in interurban 600-volt railways the maximum and all-day efficiencies of the various apparatus are approximately as given in the following table:

Apparatus	Full-load eff., per cent	All-day, eff., per cent
Step-up transformers	98	97
High-tension line	95	98
Step-down transformers	97	94
Converters	90	88
Low-tension distribution	85	88
Over-all, a-c. generator to motors	69	69

First Cost of Converter Substations. — Synchronous converters for railway purposes cost from $9 to $11 per kw., the transformers from $5 to $10 per kw., and the switchgear equipment from $3 to $11 per kw. of substation rating. The total first cost of substations is subdivided approximately as given in the accompanying table.

Item	Per cent of total
Electrical apparatus	67
Building and fixtures	17
Wiring and erection	15
Miscellaneous	1

In an approximate way the cost of substations including building, erection and installation, for 33,000-volt transmission, 25-cycle converters, 600 volts on trolley is as follows:

Station capacity, kw.	No. Converters	Capacity of each converter, kw.	Approximate cost of station
300	1	300	$15,000
600	2	300	25,000
800	2	400	31,000
1000	2	500	36,000

Cost of Operation of Converter Substations. — Labor or wages of the attendants is the principal item in the cost of operation of a substation. Supplies and maintenance form a very small percentage of the cost. In general only one man per shift is necessary, as the principal duties are to start up the machines in the morning and occasionally during the day if they drop out of step due to a short-circuit. Frequently the duties of the attendant can be combined with that of ticket seller or express agent. Where the duty is only attending to the substation, $1800 to $2000 per year may be taken as the cost of operation of a substation, allowing for the two shifts a day.

PORTABLE SUBSTATIONS. — Circumstances frequently occur under which the traffic on a certain branch of a railway is very heavy for only a few

weeks in the year, and possibly for only two or three days in the year. Moreover traffic may be exceptionally heavy on one branch for one short period and on another branch at another period. In such cases as these it would be very expensive to provide on each branch substations having a capacity to meet the heavy demand. To meet such conditions "portable" substations are used. These consist of what are practically large steel furniture cars, in which are installed one synchronous converter and the necessary transformers and control devices. Side tracks are provided at points on the branch lines and when needed this portable substation is hauled to the place desired and its high-tension terminals are connected to the high-tension transmission line, provision for which must be made in building the line, and its direct-current terminals are connected to the trolley and the rail respectively. Such a substation may be of great convenience and value for interurban roads where summer parks, circuses and athletic games occasionally render traffic conditions difficult. The car is limited in its size by the standard clearance outlines of the roads over which it must pass. It usually weighs, with all its equipment, about 75 tons. Apparatus having a capacity of 500 kw. may be installed in such a car and the primary voltage may be as high as 33,000 volts (*see article on Switchgear Equipment*).

HIGH-VOLTAGE DIRECT-CURRENT SUBSTATIONS. — Several electrical railways at present are operated at 1200, 1800 and even 2400 volts d-c. between trolley and ground. For this purpose power is transformed from alternating current by means of either motor-generator sets or synchronous converters. At first the motor-generator set was considered more fitted to the purpose as the design of the commutator is not as restricted in a generator as in a converter and the interpole made it possible to operate at a high potential between brushes. Subsequently, synchronous converters with interpoles and operating at 25 cycles were developed, and are now in successful operation. At first two 600-volt machines were connected in series to give 1200 volts. Later, machines were developed which would give 1200 volts on each machine and these became available for 2400 volts by connecting two in series. A number of installations of this type are in successful operation at present.

ALTERNATING-CURRENT SINGLE-PHASE SUBSTATIONS. — For a single-phase railway operating at a high voltage on the trolley (11,000 usually) it is not necessary to place substations as near together as in the case of d-c. systems. However, even with 11,000 volts on the trolley, there comes a limit to the length of road which may be supplied from one feeding point. In this case it becomes necessary to step up the voltage at the power station to 33,000 or some higher voltage and step down again to the trolley voltage at distant substations. A substation for this purpose need contain only transformers and control devices. It is much simpler and less expensive than the converter substation. It has even been a matter of discussion as to whether such a substation would require continual attendance to maintain proper operation. This is, however, a matter which must be decided by local conditions. If oil-cooled transformers are used there is no moving apparatus in the station, and the only need of an attendant is in case of accident or to reset a circuit breaker in case it goes out as a result of an overload.

SWITCHBOARDS. — (*See also Bus-Bars; Circuit Breakers; Meters; Switches; Switchgear Equipment for Power Stations.*) The term switchboard formerly comprised all apparatus in that portion of an installation devoted to collecting, measuring and distributing the electric energy. In small plants all of the switchgear is mounted on a single structure which is then called the switchboard. In large modern plants the control and measuring pieces of apparatus are frequently mounted on one structure, and the busbars and switches on another. In such cases the term switchboard is confined to the structure, whether panel, pedestal, or desk type, which supports the meters, controlling handles and similar devices. The following article discusses the arrangements of apparatus on representative switchboards selected to illustrate the general trend of switchboard design. For a description of the respective structural arrangements required by direct control and distant control, see the article on *Switchgear Equipment in Power Stations*.

CONSTRUCTION OF PANEL SWITCHBOARDS. — The earliest so-called "panel" boards were made of wooden panels. The various switches, instruments, etc., each on its own base, were attached to the wooden panel, with the wiring on either the front or the rear. The next step in advance was the elimination of the wooden panel and framework. Each piece of apparatus was mounted on a marble slab, which was arranged for placing in an angle-iron framework, and switchboards were made by combining the necessary ammeter, voltmeter, switch and rheostat slabs to make the panels for the different generators, feeders, etc. This form of construction was entirely fireproof but various disadvantages ultimately lead to its being superseded by the modern design of panel switchboards with the apparatus grouped on panels made of one or more comparatively large pieces of marble, or slate.

The design of modern panel switchboards has undergone the standardizing process that has been applied to all electrical apparatus. By careful study of requirements the vast majority of plants of moderate size can be equipped with control switchboards that are made up by assembling standard panels.

Framework of Panel Boards. — In general the framework of the standard switchboard may be divided into two types. The cheaper and smaller boards are mounted on a framework of gas pipe, and usually comprise panels about 4 feet high with a space between them and the floor. The larger and more expensive boards have a total height of about 7 feet 6 inches, extend down to the floor, and are provided with an angle iron or pipe frame.

Gas-pipe Frames. — Although the gas-pipe construction is considerably lighter than the angle-iron construction it has been found amply secure for these smaller switchboards and in fact some manufacturers use gas-pipe construction for most of their larger switchboard installations. Where the number of panels does not exceed four or five the complete board can sometimes be shipped with the panels attached to the framework and most of the small wiring, etc., undisturbed, but if the boards are large ones the panels and frame are shipped separately.

Angle-iron Frames. — For larger and more expensive panels a framework of angle-iron construction is frequently used. Each panel of a total height of 90 inches is provided with 2 by 3 by ¼ inch or some similar section angle irons with the narrow web bolted to the panel. These angle irons extend from the bottom of the panel to within ½ inch of the top. The vertical angles on adjacent panels are bolted together through the 3-inch web. They are provided with corner angles for bolting at the bottom to a 6 by 2-inch channel iron forming the base of the frame and at the top to two ½ by 1⅜-in. iron strips. The channel iron and the top irons are made continuous the entire length of the

board, if this is not over 16 feet. Each panel is shipped bolted to the two angle irons that form its individual frame, which obviates any necessity of disconnecting the wiring between the various slabs making up the panel. This practice of shipping the framework with the panels reduces to a large extent the breakage due to rough handling and facilitates the erection of the board at its destination.

Switchboard Panels. — After trying various materials practically all switchboard builders have adopted either slate or marble, although in a few instances soapstone, brick or steel has been used. The marble used in switchboards is usually of the grade known as "Blue Vermont," although occasionally "White Italian," or "Pink Tennessee" is used.

Comparison of Slate and Marble. — Where switchboard panels are to be given a black finish the choice of slate or marble is largely a question of cost and insulation. Slate is considerably cheaper and somewhat stronger than marble and where the voltage of live metal parts mounted on the panels does not exceed 750 volts it answers just as well. This makes it suitable for all boards except those having ground-detector receptacles, fuse blocks or similar apparatus mounted on the material of the panel and connected to a circuit of 1100 volts or more.

Finish Used on Panels. — The marble is sometimes polished on the front face and bevels, and occasionally on the edges and back. The present standard finish for marble is a dull black marine finish applied to honed panels. Ordinary slate, owing to its irregular color and marking, is usually given an enamel or marine finish and natural black slate is given an oil finish.

Dimensions of Two-piece Panels. — The total height of standard switchboard panels is 90 inches from the channel iron. The division resulting in a 25-inch lower slab as furnished by one company is due to the fact that these particular dimensions were best adapted to the line of switches, circuit breakers, meters, etc., which were in use at the time the standard railway switchboard panels were first brought out. The lower 25-inch slab was used for rheostat face plates having the contacts and contact mechanism on the front of the panel. In order to correspond with the old d-c. panels the a-c. panels were brought out having a lower slab 25 inches high and a main slab 65 inches high. The similar design of another company provides panels with slabs 62 inches and 28 inches high which dimensions were suited to their apparatus at the time of standardization.

Dimensions of Three-piece Panels. — When the present standard brush-type, carbon-break circuit breaker was designed it was found advisable to mount this breaker at the top of the panel in order to take advantage of the tendency of an arc to rise. As all these standard breakers up to 3000 amperes capacity required a vertical space of less than 20 inches, it was soon decided to divide the main upper 65-inch panel into two slabs, one portion being 20 inches high to contain the circuit breaker and the other portion 45 inches high to contain the meters, switches, etc. For this reason the standard d-c. panels of one maker, both for railway and for light and power work, are divided into three slabs, the upper 20 inches high, the middle 45 inches and the lower 25 inches. Nearly all switchboard builders are now following this practice of putting heavy circuit breakers on separate slabs.

TYPICAL DIRECT-CURRENT SWITCHBOARDS. — A few standard equipments are described in the following paragraphs.

Small Isolated Plant Switchboards (Fig. 1). — Where there is only a single d-c. generator of small capacity with one or two feeder circuits and there is little likelihood of additional equipment being needed, a board such as shown in Fig. 1 can be used. This panel, 36 inches high by 16 inches wide, is provided with a

polarized ammeter and voltmeter 5 inches in diameter, single-pole carbon breaker, 2-pole main switch, field rheostat in the generator circuit, and switches with fuses in the feeder circuits. This type of board is limited to 10 kw. at 125 volts and 20 kw at 250 volts.

2-Wire Switchboards (Fig. 2). — For the control of small capacity, d-c. generators operating in parallel on a 2-wire, d-c. circuit the connections are made

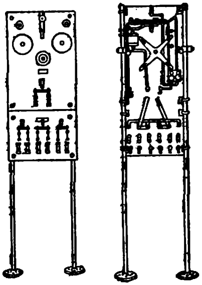

Fig. 1. Direct Current Isolated Plant Switchboard

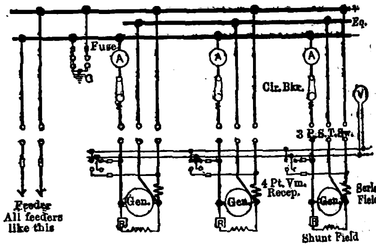

Fig. 2. Connections of 2-wire Switchboard

as indicated in Fig. 2. Each generator is provided with a 3-pole, single-throw switch, a single-pole circuit breaker, an ammeter, and rheostat and a 4-point voltmeter receptacle used for connecting the voltmeter to any machine. Each feeder is provided with a 2-pole switch with inclosed fuses, and a lamp ground detector is connected across the bus-bars.

3-Wire Switchboards. — Fig. 3 shows the diagram of connections for a typical d-c., 3-wire installation and indicates the method of deriving the neutral connection from the middle point of auto-transformers; the use of series fields

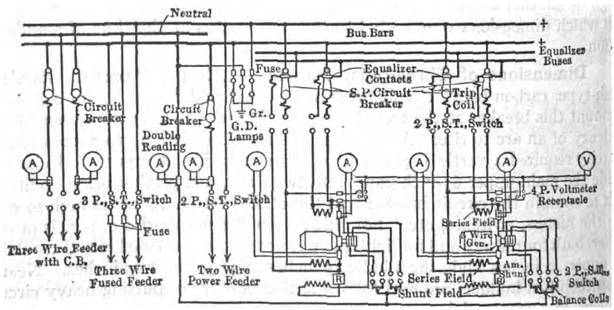

Fig. 3. Connections of 3-wire Switchboard

in the positive and negative circuits; the placing of the ammeter shunts on the terminal boards of the machines so as to be connected inside the series fields; and the 4-pole circuit breakers or the equivalent two single-pole breakers with equalizer contacts to open the positive, positive equalizer, negative and negative equalizer circuits.

Double-bus Railway Switchboards. — For direct-current railway or tramway work at about 600 volts it was for a long time the standard practice to bring both the positive and the negative leads from the generator to the switchboard and to locate both the positive and negative busbars on the switchboards, such boards being called "double-bus" boards. With these boards it was customary to use compound-wound d-c. generators with the series fields in the armature circuit which connected to the overhead trolley. The equalizer connection was usually made through a switch at the machine and the equalizer connection ran from one machine to the other without going to the panel board.

"Single-bus" Railway Switchboards (Fig. 4). — Modifications in this class of switchboards came from placing the series fields in the grounded circuit instead of in the trolley circuit and running only one polarity, usually the positive, to the switchboard. The equalizer switch and the negative switch, if the latter is used, are mounted at the machine. Fig. 4 is a typical diagram of a single-bus switchboard with only one polarity on the board. The advantages of this single-bus arrangement are greater security against short circuits, narrowing of the generator panels with consequent reduction in length of switchboard, reduction in amount of cable required, and the use of bare copper strap or cables between machines for the negative and equalizer busses.

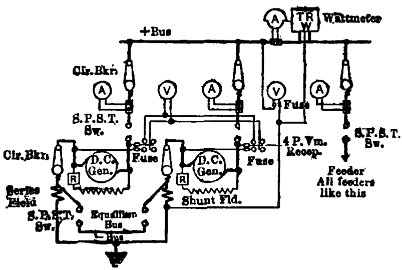

Fig. 4. Connections of Railway Switchboard

Rotary-converter Switchboards. — For rotary converters or motor-generator sets the panel switchboard, if such is used, takes care of both the d-c. and a-c. circuits, which usually are controlled by separate panels. The d-c. panels are practically the same as those used for d-c. generators. The a-c. panels usually correspond with a-c. feeder panels and control the high-tension side of the step-down transformers used with the rotary, where the rotary is made self-starting from the a-c. end. With such machines, in addition to the panels for the high-tension side of the transformers, it is customary to furnish a small slab mounted near the step-down transformers which is used for connecting the rotary to low-voltage taps for starting and then to the full-voltage taps for running. In many rotary-converter installations a combination of direct control for the d-c. circuits and distant control for the a-c. circuits works out to advantage.

Mercury Rectifier Switchboards. — Another combination of a-c. and d-c. equipment met with in switchboard practice is that furnished for mercury rectifiers used in conjunction with constant-current d-c. arc lights fed from a constant-potential a-c. system. The apparatus supplied usually comprises a two-pole oil switch with fuses for the primary circuit of the regulator, plug switches in the secondary circuit, a mechanism for tilting the bulb of the mercury rectifier, and a high-voltage d-c. ammeter placed under a glass cover. The switchboards furnished with low-tension rectifiers are of similar arrangement, except that they are fitted with low-tension meters and switches, and have a single-pole starting switch which automatically applies a rheostat load for starting.

Other Arc-light Switchboards. — For use with d-c. series arc generators, switchboards are frequently supplied with a multiplicity of plug switches to

permit any generator or feeder circuit to be connected in series with any other circuit or circuits. (*See Switches.*)

Exciter Panels, although d-c., are almost invariably combined with and form part of a-c. switchboards. The d-c. sections of the board are naturally considered with the a-c. sections and made to correspond with them in general design. Exciter panels are either single or double, depending on whether they control one or two machines. Usually no fuse equipment or other automatic protection is provided with exciter panels, as the sudden opening of the field circuit due to the blowing of an exciter fuse or the tripping of an exciter breaker is apt to injure the insulation of the generator and cause far greater damage to the plant than the overloading or short circuiting of an exciter. Where there are several large exciters operating in parallel with each other or a large storage battery, it is occasionally considered good practice to furnish reverse-current circuit breakers in the exciter circuits.

TYPICAL ALTERNATING-CURRENT SWITCHBOARDS. — Some standard equipments are described and illustrated in the following paragraphs.

Small Low-voltage A-C. Boards (Fig. 5), made for circuits of not over 600 amperes capacity at 500 volts, are usually built of panels 48 inches high on pipe frames. Each a-c. generator may have its own exciter as shown in Fig. 5, or the exciters may be operated in parallel and controlled from exciter panels. As shown on this diagram the d-c. circuits are taken care of by an exciter rheostat, a generator rheostat and a 2-pole field switch with discharge resistance. Each a-c. generator is provided with a 3-pole single-throw knife switch, three ammeters, an 8-point voltmeter receptacle, and a synchronizing receptacle and plug. Each feeder has a 3-pole switch and an ammeter.

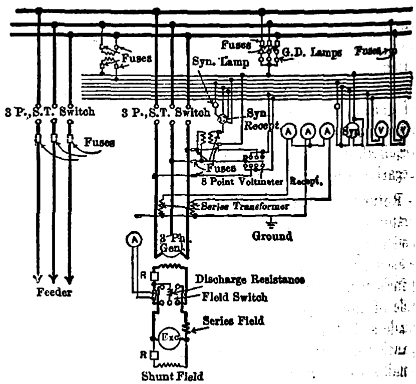

Fig. 5. Connections of Low-voltage Alternating-current Switchboard. (Only one Generator Shown)

A lamp ground detector and a voltmeter are connected in such a manner that the voltage can be read across any phase of any machine. In this diagram lamps are used for synchronizing.

Small High-voltage A-C. Boards. — A similar arrangement of panels may be used for small-capacity high-voltage switchboards, using oil switches in place of knife switches in the generator and feeder circuits, and operating the voltmeter and lamp ground detector from potential transformers.

Large Low-voltage A-C. Boards. — Fig. 6 shows some typical panels for low-voltage a-c. circuits where the cost of equipment is kept to a minimum by simplifying the equipment of instruments, omitting the sub-panels (the lower sections of slabs), and using ornamental cast-iron legs to cover the portion of the framework which projects below the main panel. The panels shown are selected as representative of this type of construction, not as an actual switchboard. The bracket instruments comprise the synchroscope and two volt-

meters, one for the bus and one for the machines. The first panel at the left-hand end is a 1000-ampere 2-phase generator panel with double-throw

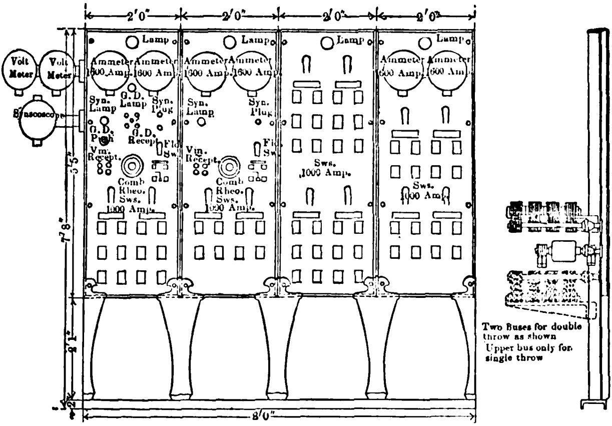

Fig. 6. Low-voltage Alternating-current Switchboard Panels

main switches for connecting to either of two sets of busbars. The panel is also provided with illuminating lamp, two ammeters, 6-point voltmeter receptacles, synchronizing lamp receptacles, plug ground detector receptacle, lamp, push-button rheostat mounting, and field switch. The second panel is a corresponding single-throw generator panel, and the two remaining panels are double-throw and single-throw feeder panels. The side view shows the arrangement of the bus-bar supports, switch studs and connections.

For more important installations sub-panels are furnished. The generator equipment then includes field ammeters and indicating wattmeters, and a synchroscope is provided for paralleling the generators.

Large High-voltage A-C. Boards (Fig. 7) are almost invariably provided with oil switches (or oil circuit breakers), mounted either on the switchboard or apart from it. All a-c. instruments are operated from current and potential transformers. Fig. 7 gives the diagram of a typical switchboard consisting of one exciter panel, two generator panels, and one feeder panel. The connections are shown as though viewed from the back of the board and the leads from the current and potential transformers are bunched into cables.

Station Voltmeter and Synchronizer. — On this switchboard there are 2 voltmeters and 1 synchroscope mounted on swinging brackets at the end. The inner voltmeter is operated through cable 4B from potential transformers connected to the bus. These transformers are used also for the potential circuits of the generator wattmeters and for synchronizing. The other voltmeter is connected through suitable receptacles to the potential transformers of any machine. The synchroscope and synchronizing lamps are operated by inserting the suitable plug in the synchronizing receptacle. When the plug is so inserted, it connects the three inner segments by means of one ring. At the same time the bus transformer is connected to the bottom terminals of the synchroscope and the generator transformer to the top terminals. A lamp at the synchroscope and one on the particular generator panel are connected in parallel with the synchroscope and flash up and down in step with it.

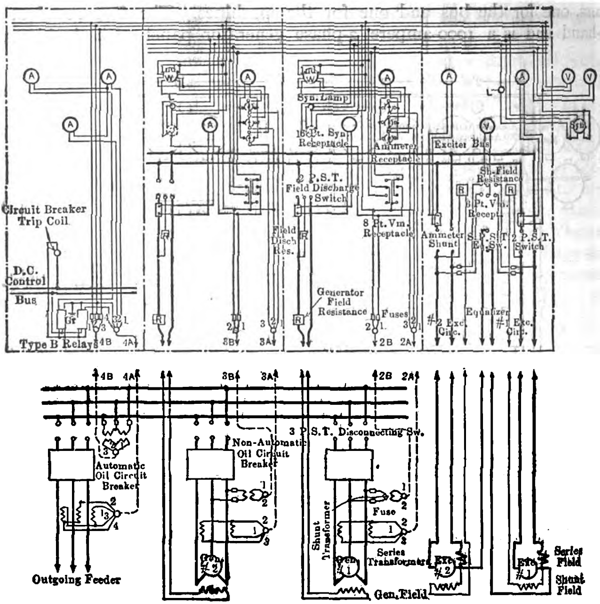

Fig. 7. Connections of High-voltage Alternating-current Switchboard

Exciter Panel. — The first panel (on the right looking at the rear) controls 2 exciters and is provided with 2 2-pole main switches, 1 single-pole equalizer switch, 2 ammeters operated from shunts, 2 rheostats, and 1 exciter voltmeter connecting to either exciter by means of a 6-point receptacle and a 4-point plug.

Generator Panels are each equipped with a 3-pole non-automatic oil circuit breaker with disconnecting switches, 2 current transformers, 1 potential transformer, 1 2-pole field switch with discharge resistance, 1 field ammeter operated from a shunt, 1 polyphase indicating wattmeter, 1 a-c. ammeter with three receptacles for reading the current in any phase, 1 8-point voltmeter receptacle, 1 6-point synchronizing receptacle, and 1 synchronizing lamp.

Feeder Panel. — This is equipped with 1 3-pole automatic oil circuit breaker, 3 disconnecting switches, 3 current transformers, 1 pair of single-phase over-load relays, and 3 ammeters. This system is a simple one with 1 set of exciter bus-bars and 1 set of a-c. bars with a moderate number of instruments, but even this gives some idea of the complexity met with in the detail diagram of a large and complicated a-c. switchboard.

Large Distant-control A-C. Switchboards. — Where the amount of power to be controlled is large or the voltage is above 3300, it is customary to mount the oil circuit breakers apart from the board and to operate them either mechanically or electrically. On these boards the usual equipment of instruments is mounted at the top of the panel, the switch-control handles are in the middle and the time-limit relays at the bottom. Targets and signal lamps to

indicate the condition of the feeder are furnished with electrically operated boards.

SWITCHBOARDS OF PEDESTAL AND POST TYPE. — Where the number of generators is comparatively small in comparison with the number of feeder circuits, it is frequently of advantage to use control pedestals and instrument posts for the generator circuits and to take care of the feeder circuits by means of a panel switchboard. The instrument posts and control pedestals can readily be added with additional machines, without disturbing the symmetry of the arrangement.

Control Room of Ontario Power Co. — An example of this general arrangement is the control room of the distributing station of the Ontario Power Company at Niagara Falls, Ontario (*El. Rev. & W. El., 1911, Vol. 59, p. 1036*), for the control of seven 8770-kv-a., 12,000-volt, 3-phase generators, with banks of three 3000-kv-a. transformers stepping up to 60,000 volts. In this room there are the following switchboards: 1 panel board to control the 60,000-volt feeder circuits running to Rochester, Syracuse, etc., 1 control pedestal and 1 instrument post for each of the 12,000-volt generators; and 2 smaller pedestals for the control of the exciter circuits.

Each of the seven control pedestals is equipped with push-button control for the generator field rheostats and is provided with a white signal lamp which lights up when the field circuit is closed. There are 2 electrically operated oil circuit breakers in each main generator circuit, one being placed in the power house and the other in the distributing station. The circuits from the generator, after passing through these two breakers, are connected by a breaker to one 12,000-volt bus-bar in the distributing station, or can pass through another breaker to a common connection, where it branches and passes either through a breaker to a second 12,000-volt bus-bar or through a breaker to the low-tension side of the step-up transformers. Each circuit breaker is controlled from the generator pedestal. Suitable synchronizing lamps and receptacles are also placed on these pedestals. The pedestals are 5 feet high and each occupies a floor space of approximately 24 inches by 14 inches. Each post is provided with a single-phase synchroscope, a frequency meter, a three-phase power factor indicator, and transformer and generator ammeters. The total height of this post is 9 feet and the width occupied by the meters is 2 feet 7⅝ inches.

CONTROL DESKS (Figs. 8 and 9). — Where it is desired to have a very compact arrangement and to control the generators and feeders from the same switchboard, the control desk has many advantages; particularly where a group system of circuits is used and it is desirable to have a miniature bus-bar to show the general scheme of connections and the arrangement of circuits in use. The desk has mounted on it the field switches, field rheostat handles, and small switches for operating electrically the various controllers, circuit breakers, etc. The field switches and rheostats may also be operated electrically.

Location of Instruments with Control Desks. — The instruments can be mounted either on panels forming the back of the control desk (Fig. 8), or on an instrument frame back of and usually higher than the top of the control desk (Fig. 9), or on instrument posts. The grouping of the instruments is made so far as possible to correspond with the grouping of the control devices. As it is possible for the station operator to become confused in determining the instruments belonging to a certain generator or feeder, whose controlling devices are on the desk, card holders or name plates are placed both on the desk and on the panels. Where instrument panels form the back of the control desk, the instruments as a rule are arranged to correspond in location with the controlling devices for the same circuits. When an independent instrument frame is used,

this is usually arranged at such a height that the station operator standing at the control desk can look over the top of the desk and under the bottom of the instrument frame, out into the station, and readily observe the operation of the machine which he expects to control.

Control Desk with Instrument Panels. — Fig. 8 shows the plan view, front elevation, and end view of a control desk having instrument panels which

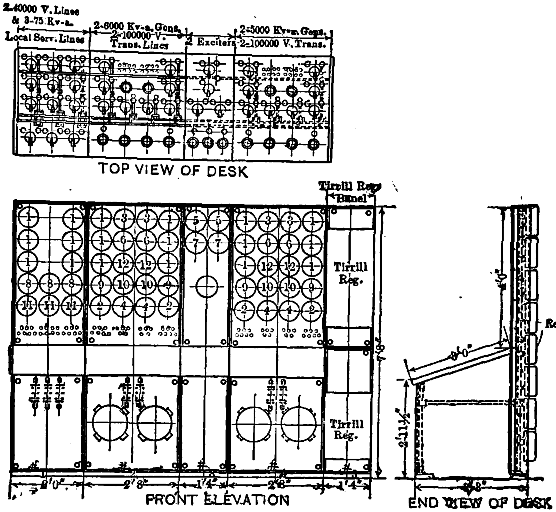

Fig. 8. Control Desk with Instrument Panels

come down to the top of the horizontal section of the desk. This desk when fully equipped will take care of two 300-kw., 250-volt, waterwheel-driven exciters; four 6000-kv-a., 4000-volt, 3-phase generators; four banks each of three 1750-kv-a., single-phase transformers stepping up to 100,000 volts; three 1750-kv-a., 3-phase transformers stepping up to 40,000 volts; four 100,000-volt transmission lines and two 40,000-volt transmission lines. The miniature bus on the face of the desk shows the various connections made by the breakers. In this plant the exciter circuits and the field circuits of the generators are controlled by electrically operated switches, as are also the main circuits of the generators, transformers and transmission lines.

Control Desk with Separate Instrument Frame. — Fig. 9 shows the plan view, elevation and side view of a control desk provided with 7-inch diameter round pattern meters located on an instrument frame back of and above the desk. The height of the instrument frame is 7 feet 8 inches, which corresponds to the height of standard 90-inch switchboard panels mounted on the usual 2-inch channel iron base. This control desk with a total length of 12 feet, when fully equipped, is to take care of six 10,000-kv-a., 3-phase, 6600-volt generators, six banks each of three 3333 kv-a. step-up transformers, and four 110,000-volt transmission lines.

As shown by the miniature bus system placed on the top of the control desk, each of the six sections intended for a generator and its bank of transformers is provided with a generator ammeter, transformer ammeter, generator indicating

wattmeter, power-factor meter, voltmeter, and field ammeter, as well as four circuit-breaker controllers. Each generator, with the low-tension side of its

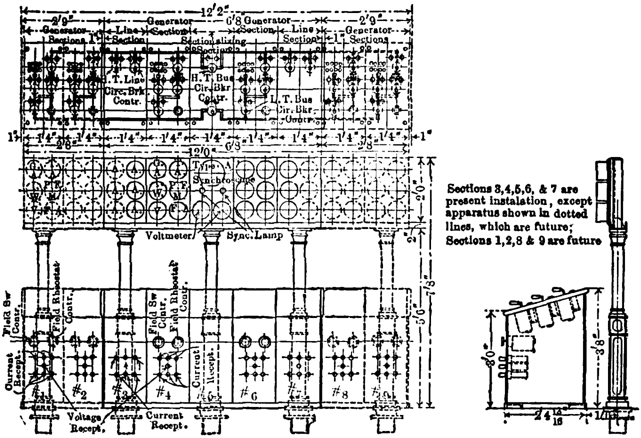

Fig. 9. Control Desk with Separate Frame for Instruments

bank of step-up transformers, is provided with three breakers, one in the main generator circuit connecting the generator to a generator bus, one for connecting this generator bus to a main bus, and the third for connecting the generator bus to the low-tension side of the step-up transformers. With this arrangement under normal conditions each generator will supply current to its own bank of step-up transformers, but in emergency any generator or any transformer can be connected to the low-tension bus, which is sectionalized in the middle by means of an electrically operated breaker. On the high-tension side each bank of transformers connects through a single breaker to a high-tension bus that is sectionalized in the middle by means of an electrically operated breaker. Two high-tension lines are fed from each half of this sectioned bar.

Dimensions of Panels. — The smaller panels intended for use with gas-pipe framework are made in single slabs and as a rule have a height of 48 inches and a width of either 22 inches or 32 inches, although some of the panels are smaller. As few of the smaller d-c. panels have to be made wider than 22 inches or 24 inches and as 1¼ inches is ample thickness for a 24 by 48-inch slab, the thickness of 1¼ inches has been adopted as a standard for most of the small d-c. panels. In order to secure sufficient mechanical strength the 32-inch panels are made 1½ inches thick. As these wide panels are usually required for alternating-current generator panels this thickness of 1½ inches has been usually adopted as standard for a-c. panels. For heavier panels 2-inch marble and slate have been adopted as standards for mechanical reasons. This thickness is required for the heavy switches, circuit breakers, etc., often furnished on these switchboards. When a board has both a-c. and d-c. panels the thickness of all panels is made the same.

Beveled Edges. — The edges of all panels are usually beveled to improve their appearance and to insure against chipping, as it is almost impossible to handle square-edged marble or slate slabs without injury. The front edges are ordinarily beveled with a 45-degree bevel of either ⅜ inch or ½ inch, measured

in the plane of the panel. It has also been found advisable to use a small bevel of 1/16 inch or 1/8 inch on the back edges to prevent chipping.

SPECIFICATIONS AND TESTS. — See article on *Switchgear Equipment for Power Stations.*

COSTS. — The cost of any particular type of switchboard is arrived at by summing up the costs of the various instruments, switches, etc., and adding to this the cost of the framework, slabs and wiring. The following figures are approximate only.

Gas pipe for framework....................	$0.07 per linear foot
2 by 3 by 1/4-inch angle iron................	0.11 per linear foot
6 by 2-inch channel iron..................	0.20 per linear foot
1/2 by 1 3/8-inch strips....................	0.10 per linear foot

Slabs only, without drilling	Marble	Slate
48 by 24 by 1 1/4-inch panel..........................	$5.12	$2.42
48 by 32 by 1 1/2-inch panel..........................	8.99	4.15
90 by 24 by 2-inch panel..........................	15.60	7.00

The cost of drilling, wiring and erection ranges from 5 to 25 per cent of the total cost of the board erected complete. See also article on *Switchgear Equipment for Power Stations.*

[S. Q. HAYES.]

SWITCHES. — (*See also Circuit Breakers; Switchboards; Switchgear Equipment for Power Stations; Wiring of Buildings.*) A switch is a device for mechanically opening an electric circuit. Various types of knife, drum, plug and oil switches are used; some representative types are described below.

Fundamental Requirements are (1) a switch must, when closed, carry the rated current without excessive drop, usually from 5 to 15 millivolts, or excessive heating, usually 28° C. temperature rise; (2) it must take care of overloads met in practice; (3) it must be designed to prevent or render harmless any arcs that are formed when being opened; (4) it must, when open, insulate all live parts for the maximum potential of the circuit.

KNIFE SWITCHES.— The rules of the National Board of Fire Underwriters relative to knife switches advise for pure copper blades a current density at contact surfaces of not over 75 amperes per square inch. The recommended minimum spacings between points of opposite polarity for various currents and voltages are given in the accompanying table.

Full-load current, amperes	Inches between points of opposite polarity		
	125 v. d-c.	250 v. d-c. 500 v. a-c.	600 v. d-c.
100	1¼	2¼	4½
200–300	2¼	2½	4½
400–600	2¾	2¾	4½
800–1000	3	3	4½

Throw and Poles of Switches. — A switch closing a circuit only when thrown in one position is called a single-throw switch; a switch closing a circuit when thrown in either of two positions (e.g., up or down) is called a double-throw switch. A switch closing only one side of a circuit (one blade) is called a single-pole switch; one closing both sides (two blades) is called a double-pole switch. Evident abbreviations are used, such as S.P.S.T. for single-pole single-throw; D.P.D.T. for double-pole double-throw.

Single- and Multi-blade Knife Switches. — Up to 1000 amperes in capacity knife switches are usually made with single blades. For larger capacity two or more blades per pole are supplied in order to secure sufficient contact surface without making the blades and jaws of abnormal width.

Field Switches (Fig. 1). — A modification of the standard knife switch (q.v.) as shown in Fig. 2 is furnished for use in connection with field circuits. These field switches, whether single-pole or double-pole, single-throw or double-throw, are provided with an auxiliary contact and extra jaw which are used for connecting a resistance across the field terminals before the field is disconnected from the source of supply. The field discharges through this resistance without any inductive kick such as will occur on the sudden opening of a highly inductive circuit without such a device.

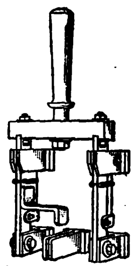

Fig. 1. Quick-break Field Switches

Auxiliary Breaks and Quick-break Attachments are furnished with knife switches in many cases so as to make it impossible to draw a dangerous arc

by opening the switch slowly. Fig. 2 shows a typical quick-break knife switch. The main-switch blade here carries auxiliary blades, which are attached to the main blades by a hinge and spring. When the switch is opened, the auxiliary blades are held in the jaws by friction until they are suddenly jerked out by the spring tension. A similar attachment is used on the field switch shown in Fig. 1.

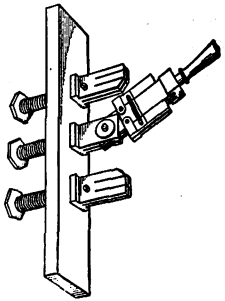

Fig. 2. Quick-break, Single-pole, Double-throw Switch

Starting Switches. — A modification of the standard knife switch is the multi-point starting switch used occasionally for starting d-c. motors, or rotaries or motor-generator sets from the d-c. end. These multi-point starting switches consist usually of single-pole, single-throw switches with several break jaws connected to various steps of the starting resistance.

Disconnecting Switches. — In all high-tension circuits it is customary to install knife-type disconnecting switches for isolating feeders, oil circuit breakers, etc., or for making various connections that do not have to be opened under load. In American practice the knife switches for 3300 volts or less are usually mounted directly on a base of soapstone, marble or similar material; for higher voltages insulators of various kinds are used to support the switch jaws. Up to 33,000 volts these disconnecting switches are made for either front connection, rear connection, or both, but for higher voltages they are almost invariably made for front connection only.

Disconnecting Switches Mounted on Pillar-type Insulators. — Fig. 3 shows a disconnecting switch designed for 13,000 volts. A similar construction is used for voltages up to 110,000. The insulators are of the pillar type and are given a dry test of three times normal voltage. On the larger sizes of this type of switch a trussed blade is furnished to secure rigid construction, and safety catches are supplied to prevent the switches jarring open. The caps holding the jaw blades are clamped to a wall or other flat structure after they are removed from the wooden templates on which they are shipped. On the 110,000-volt switch of one make the center line of the blade is 36¼ inches from the base and the jaws are 44¹⁄₁₆ inches on centers.

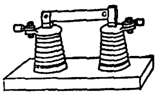

Fig. 3. 13,000-volt Disconnecting Switch

Disconnecting Switches Mounted on Suspension Insulators. — For voltages above 110,000 a type of disconnecting switch using the suspension type of insulators is often found more satisfactory. The main feature of this type of switch consists of a series of suspension-link insulators with a funnel-shaped contact at the lower end. This funnel-shaped contact can be dropped over a pin contact attached to the terminal of an oil circuit breaker or transformer. A flexible lead connects from the funnel-shaped movable contact to the busbars or other source of power.

BRUSH SWITCHES have laminated copper brushes which press against solid copper blocks when closed. They are occasionally employed instead of the usual knife switches (q.v.) to handle large currents at low voltage, since large knife switches with their large rubbing contact surfaces are sometimes difficult to manipulate. By using a toggle or similar device to increase the pressure between the laminated brush and the solid contact blocks such excellent contact is obtained that 200 or 300 amperes per square inch of contact can be used and a small potential drop and a low temperature rise still be obtained.

Electrically-operated Brush Switches. — Brush contact switches are particularly well adapted for electrical operation. As brush switches are normally held closed by a toggle, latch or similar device and as they tend to come open on the release of the toggle or latch, when electrically operated they are practically non-automatic circuit breakers (q.v.). Electrically-operated brush switches are frequently used in field circuits and in the equalizer connections of large machines where it is desired to locate the equalizer switches at the generators and to control the switches from the switchboard.

DRUM SWITCHES are often used with electrically-operated devices such as rheostats, field switches and circuit breakers. In the type shown in Fig. 4 the operating handle and direction dial are mounted on the front of the switchboard, while the contacts are back of the board and are made part of a drum-type controller. This construction removes even the d-c. operating voltage from the front of the board and readily adapts itself for use on 550-volt control circuits. This

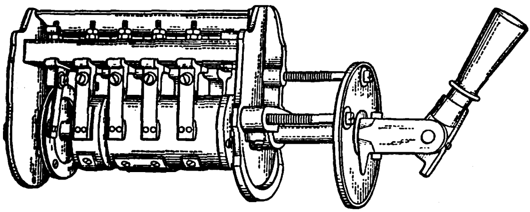

Fig. 4. Drum-type Control Switch

particular control is intended for use with oil circuit breakers. The handle is so designed that after turning to the trip position it can be lifted to stand at right angles to the plane of the dial plate when the circuit is to be put out of service for any length of time. In this position all the indicator lamps are disconnected. For use with this controller an electromechanical indicator or lamp indicator with colored prisms is supplied.

PLUG SWITCHES are commonly used for interrupting small currents at low voltages. They are particularly applicable for such uses as reading the voltage across various phases or circuits. By placing suitable receptacles on generator and feeder panels and using only one voltmeter plug switch, one instrument in a suitable location can be used for reading the voltage across any phase of any circuit without the possibility of trouble from an attempt to connect two or more circuits to the voltmeter at the same time. Other types of receptacles and plugs are used in connection with current transformers for connecting instruments into any phase of any circuit. By using suitable current and potential receptacles it is feasible to connect in testing meters for calibrating the switchboard instruments without removing them from the board.

Synchronizer Plug Switches may be fitted with auxiliary contacts so that it is impossible to close an electrically-operated breaker in a generator or similar circuit without putting the synchronizing plug in the receptacle used for synchronizing that particular circuit. The tripping circuit, however, is kept independent of the synchronizing receptacle so that the breaker may be tripped out independently of the position of the plug.

Plug Switches for Arc Service are built in capacities of 10 amperes or more suitable for use on circuits up to 10,000 volts. Each switch comprises a tube of fiber or similar material, with socket contacts at each end, and a plug consisting of a metallic rod or tube with an insulating handle. The fiber tubes are

usually mounted on the rear of the switchboard. The plug when inserted through the hole in the panel connects the contacts at each end of the tube.

Pull- or Push-Button Switches of twin type are supplied for the operation of oil circuit breakers. The switch operated by one button closes the breaker, and the switch operated by the other button opens it. All the contacts and wiring are mounted on the back of the panel, so that the operator cannot touch a live circuit. By using pull buttons in place of push buttons there is little likelihood of the attendant operating the device unintentionally when cleaning or working about the switchboard. Red and green indicating lamps with prismatic lenses are used for signals. A little red and green target located between the button shows the last movement that has been made so that if the target shows one color and the indicating lamps another it is known that the breaker has been tripped automatically.

Push-Button Switches with Signal Devices are sometimes used for transformer-type ground detectors, engine-room signals and similar equipment. These are frequently arranged as the equivalent of double-throw switches normally maintained in one position by a spring to make one set of connections, and making other connections when pushed in by hand or some mechanism.

Button and Snap Switches of various designs are used for interior lighting circuits (*see Wiring of Buildings*).

OIL SWITCH. — (*See Circuit Breakers.*) There is usually no distinction drawn between the terms "oil switch" and "oil circuit breaker," although in some cases the term "oil switch" is applied to a device with jaw or similar contacts that tend to remain closed, and the term "oil circuit breaker" is applied to a device with butt, brush, cone wedge or similar contacts that tend to come open and must be held closed by a toggle, latch or similar mechanism.

END-CELL SWITCHES. — (*See Batteries, Storage.*)

COSTS. — Switches vary so much in design that it is impossible to give a comprehensive table of costs in a limited space. The following table gives the approximate range of prices of a few typical switches.

Type	Voltage	Amperes	Cost
S.P.S.T.	110 to 600	100 to 3000	$1.65 to $72.10
S.P.D.T.	110 to 600	100 to 3000	2.87 to 103.50
D.P.S.T.	110 to 600	100 to 3000	2.67 to 144.20
D.P.D.T.	110 to 600	100 to 3000	4.47 to 207.00
S.P.D.T. quick break	110 to 600	100 to 3000	5.35 to 108.00
Disconnecting	13,000	300	9.00
Disconnecting	30,000	300	15.00
Disconnecting	60,000	300	30.00
Disconnecting	110,000	300	60.00
Brush switches	110 to 600	2000 to 10000	95.00 to 350.00
Simple plug switch	110	10	1.00
Simple snap switch	110	10	0.20

[S. Q. Hayes.]

SWITCHGEAR EQUIPMENT FOR POWER STATIONS.—(*See also Bus-bars; Circuit Breakers; Fuses; Lightning Protectors; Power Stations; Substations; Switches; Switchboards.*) This article is a summary of modern practice in regard to the arrangement of the control and switching apparatus in generating stations, transforming stations and converting stations. The special building arrangements to suit the switching apparatus are also discussed.

In the earliest plants the switchgear, which then comprised only knife switches, plugs, fuses and lamps, was scattered around the station in a more or less haphazard way, or possibly assembled on one of the walls, so that practically no space was allotted to it that could possibly be used for any other purpose. The next step with increasing amount of auxiliary apparatus involved the placing of the switchgear on a panel switchboard near the wall where very little room was taken up by it. As stations grew still larger, proportionately more space had to be allotted to the switchgear, until in the modern high-voltage, large-capacity plant, one portion of the building, or in some cases a special building, is assigned to the switchgear and designed especially for its proper housing.

As regards switchgear equipment power stations may be classified as follows:

The switching requirements of the several classes are treated in the sections following.

DIRECT-CONTROL SWITCHGEAR IN GENERATING STATIONS.—Direct-control panel switchboards are usually installed for a-c. or d-c. lighting, power and railway service of low voltage and moderate size. The switchboards for such plants are of the panel type and may be located on the station floor, on a platform or in a gallery. All the switching appliances are mounted directly on the panels of the switchboard. With such equipment it is fairly simple to locate the switchboard in such a manner as to reduce to a minimum the amounts of connecting cables and similar material that depend on the relative position of the switchboards and generators.

The amount of space required and the amount of cables, bus-bars and wiring needed in a direct-current railway generating station can be reduced to a minimum by arranging to have only one polarity, usually the positive, on the switchboard, and to place the negative and equalizer busses in the basement or in a conduit near the machine, locating equalizer and negative switches at the machine.

DISTANT-CONTROL SWITCHGEAR IN A-C. GENERATING STATIONS DISTRIBUTING AT GENERATOR VOLTAGE.—In stations that distribute current at the generator voltage there are three usual locations for the bus-bars, oil circuit breakers and control apparatus, depending principally on the amount of space needed for this portion of the installation. These locations are: 1. at the end of the building; 2. at the side of the building, and 3. in a separate switch-house.

Location of Switchgear. — The end of the building is a favorite location for the switchgear when the number of feeders is such that this location provides sufficient space for the breakers and the bus-bars, making due allowance for probable future additions. With this arrangement it is customary in large plants to provide a number of galleries for the switching equipment. The switchboard is usually placed on one of the upper galleries so that the station attendant can readily watch the operation of the machines which he is controlling.

Where the end of the building does not provide sufficient space the switching equipment is frequently located along one of the side walls, usually the side remote from the boiler room in a steam station, or from the incoming penstock in a hydraulic station. The switching equipment when arranged in one or more galleries along the side of the building can easily be extended, as the lengthening of the building provides for the switchgear proportionately with the space available for the generating equipment. With this arrangement it is usually customary to locate the generator breakers directly opposite the individual machines and to run the bus-bars the length of the station; the length of the generator leads will then be reduced to a minimum and it is sometimes possible to use bare conductors for these leads. The switchboard itself, if electrical operation is provided, may be located either on one of the side galleries or at the end of the building in such a position that the switchboard attendant can readily watch the operation of the machines which he is controlling.

An extension of this scheme of utilizing the side walls is to provide a separate switch-house and to control all of the apparatus electrically from a switchboard in the main building or from a switchboard in the switch-house as preferred.

Structures for Bus-bars and Circuit Breakers. — The arrangement of the supporting structures for bus-bars and circuit breakers is influenced chiefly by the voltage and capacity of the circuits. For circuits of moderate capacity and 3000 volts or less, mechanical control is usually employed, though electrical control is sometimes used; for circuits of large capacity or of higher voltage than 3000, electrical control is practically universal.

Structures for Mechanical Control. — Fig. 1 shows a typical arrangement of distant mechanical control applied to circuit breakers mounted on the wal or on a metal framework. The view shows a section through a 2300-volt, 3-phase generator circuit. Each circuit is provided with a 3-pole oil circuit breaker which can be connected to the three-phase bus-bars supported on the wall brackets. Sprocket-operated face plates with suitable resistors are located in the basement to allow for the regulation of the voltage on the generators. The current and voltage transformers for the instruments are located back of the board on a suitable framework or on the wall.

Structures for Electrical Control of Moderate Capacity. — Fig. 2 shows a section and the front and rear elevations of a part of the structure for use with the breakers and bus-bars for the control of four 500-kw., 2300-volt, 3-phase generators, nine 3-phase feeders and six single-phase feeders. Though the capacity and voltage of these machines would have permitted the use of hand-operated oil circuit breakers, other considerations caused the adoption of electrical operation for the breakers and of inclosed bus-bars. The relative locations of the circuit breakers, disconnecting switches, series transformers, shunt transformers, bus-bars, etc., are indicated in the cut. The bus-bars of laminated copper strap are supported on petticoat insulators, and porcelain floor tubes are used for insulating the leads where they pass through the back wall of the structure. The breakers here used are self-contained and all three poles are in the same compartment. The disconnecting switches are mounted directly on soapstone bases.

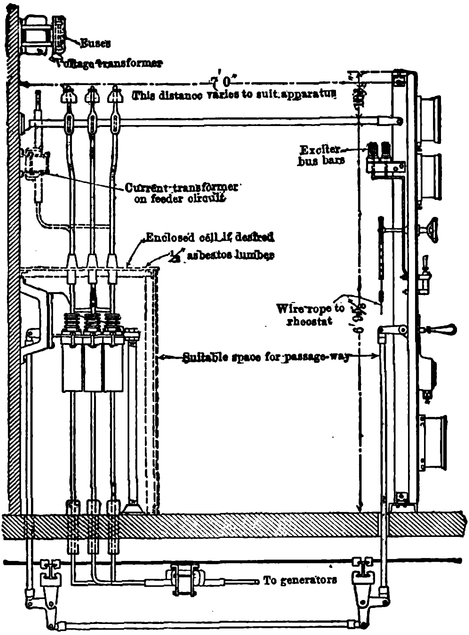

Fig. 1. Structure for Distant Control of 2300-volt, 3-phase Circuit

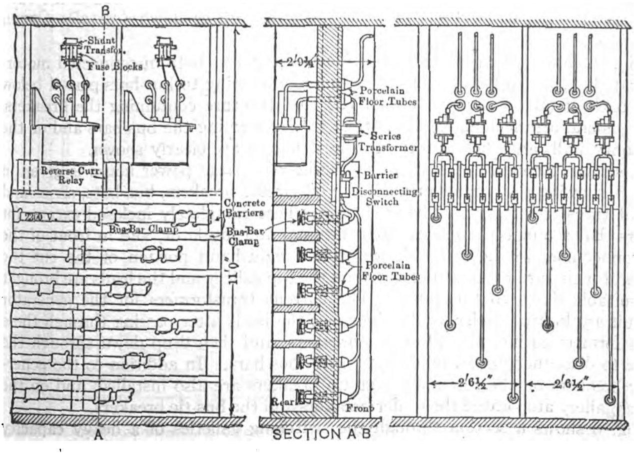

Fig. 2. Structure for Electrical Control of 2300-volt, 3-phase Circuit

The front, side and rear views of a structure for 3-phase, 6600-volt solenoid-operated oil switches of moderate breaking capacity are shown in Fig. 3. The fireproof masonry compartments and bus-bars, connections, etc., are separated

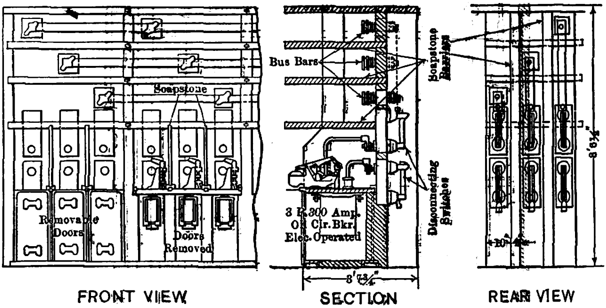

Fig. 3. Structure for Electrical Control of 6600-volt, Solenoid-operated Oil Circuit Breaker

by shelves, walls, septums, etc., in such a manner that no two conductors of opposite polarity are in the same compartment. The bus-bars of laminated copper strap are supported on the insulators that act as bushings for the leads through the walls. The disconnecting switches, partly front connected and partly rear connected, are mounted on porcelain pillars placed on soapstone bases and arranged for completely isolating the breaker.

Structures for Electrical Control of Large Capacity (Figs. 4 to 6).—For larger capacity plants distributing at the generator voltage there are in use two principal types of oil circuit breakers. With motor operation the leads are usually brought out at the bottom of the oil tanks, and with solenoid operation usually at the top. In the latter case the leads are carried through the back wall so that the connections may be run either up or down (*see also Circuit Breakers*).

Fig. 4 shows the typical ways of arranging the bottom-connected motor-operated 13,200-volt oil circuit breaker for connecting to bus-bars placed below (A), back of (B) or independent of (C) the structure containing the breakers. The general arrangement of the copper tubing forming the bus-bars and of the masonry walls and shelves forming the structure are clearly shown.

A section through the switching galleries of a large power house is given in Fig. 5, showing the arrangement of the oil circuit breakers, bus-bars, series and shunt transformers, etc. The busbars are here completely inclosed except for doors that are placed opposite each terminal and insulator, and in front of the disconnecting switches. As shown in the right-hand portion of the cut the generator circuit breakers are located on the top gallery and the leads are brought in suitable ducts to this point. The current transformers for the generator circuit are located under a false floor and the leads after passing through these transformers go into the oil circuit breakers, and then drop down through the floor to disconnecting switches and to the bus-bars. In addition to the generator breakers on the top gallery, group breakers are also installed, and on the lower gallery are located the feeder breakers and the bus-tie breakers.

Fig. 6 shows a section through the switching galleries of a heavy capacity 12,300-volt, two-phase generating station. This station controls the necessary switching equipments for the control of eight 8000-kv-a. turbo-generators and

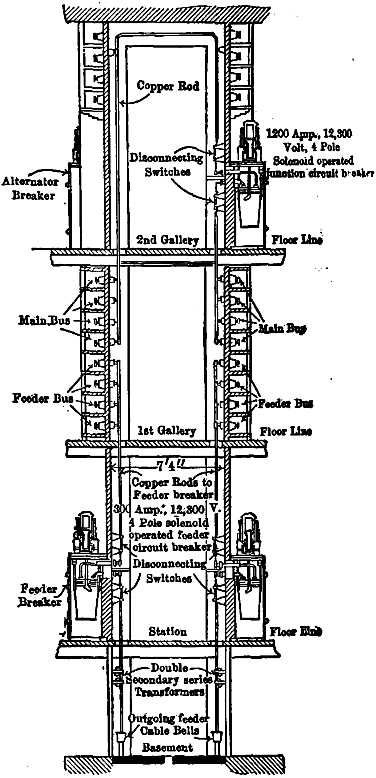
forty feeders with a large number of local service circuits. The connections are so made that each generator feeds through its own circuit breaker on to a generator bus, which can be connected through a second breaker to the main bus or through either of two other breakers to two sets of group busses, each group bus supplying current to five feeder circuits. The generator bus-bars are located directly above the breakers in the upper gallery. The main bus-bars are the top sets on the middle gallery and the feeder group bus-bars are the lower sets on the middle gallery. The bus structures are arranged back to back in such a manner that the main bus-bars form one continuous ring, sectioned by means of knife switches and circuit breakers, while the group bus-bars can be connected to form a second ring.

The designs shown in Figs. 5 and 6 show one of the advantages resulting from the use of top-connected breakers with the leads brought out through the back wall, namely the possibility of locating the bus-bars between breakers on two different galleries.

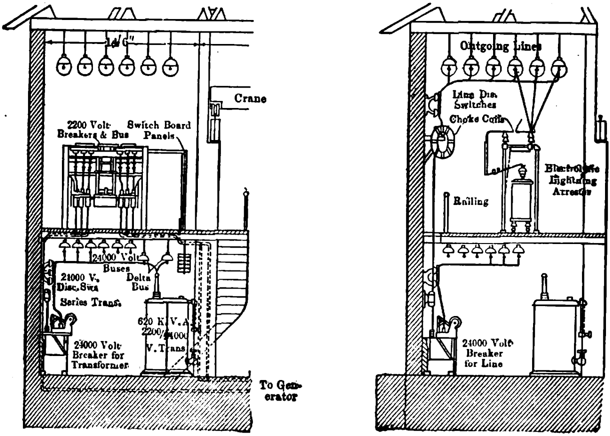


SECTION AT B-B

Fig. 6. Switchgear Arrangement for a 12,300 volt, 2-phase System

SWITCHGEAR IN GENERATING STATION WITH STEP-UP TRANSFORMERS. — Fig. 7 shows two sectional views through the switchgear section of a generating station which contains four 1875 kv-a. banks of single-phase transformers stepping up from 2200 to 24,000 volts and four 24,000-volt feeder circuits. The generators and exciters with their water wheels occupy one side of the station, and the transformers and switching equipment occupy the other side. The panel switchboard with the electrically operated 2200-volt circuit breaker in the generator circuit and the low-tension side of the step-up transformers are placed on the upper gallery. The step-up transformers with 24,000-volt electrically-operated breakers and the 24,000-volt bus-bars are all placed in the lower gallery. At each end of the upper gallery provision has been made for locating the choke coils, disconnecting switches and lightning arresters for the 24,000-volt feeders.

Switchgear Equipment for Large Hydroelectric Station. — In Fig. 8 is given a sectional view through a generating station with two 500-kw., 250-volt



Generator Connections | Line Connections

Fig. 7. Switchgear Arrangements for a 24,000-volt Station

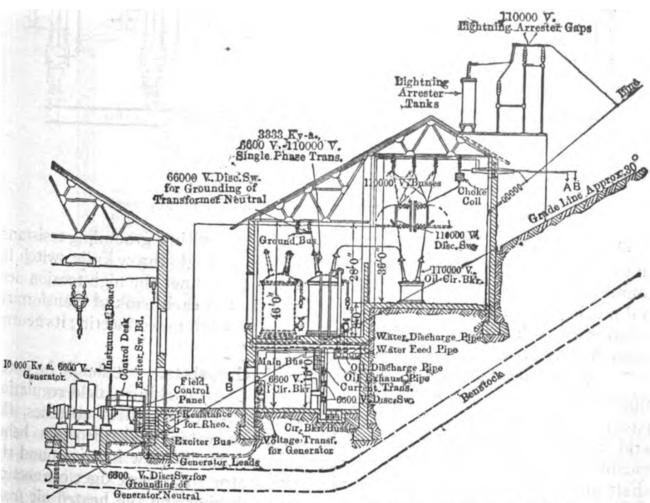


Fig. 8. Switchgear Arrangement for a 60,000-kv-a., 110,000-volt Hydro-electric Station

exciters; six 10,000-kv-a., 6600-volt, 3-phase generators; six banks each of three 3333-kv-a. single-phase transformers with delta connection on low-tension side and star connection on high-tension side; and four 20,000-kv-a., 110,000-volt, 3-phase transmission lines. The diagram of connection for this station is shown in Fig. 9.

Bus Connections. — Each generator as shown in Fig. 9 is normally used with its own bank of step-up transformers. Three circuit breakers, however, are provided with each transformer and generator group so that, if desired, any generator or any bank of transformers may be connected to the 6600-volt

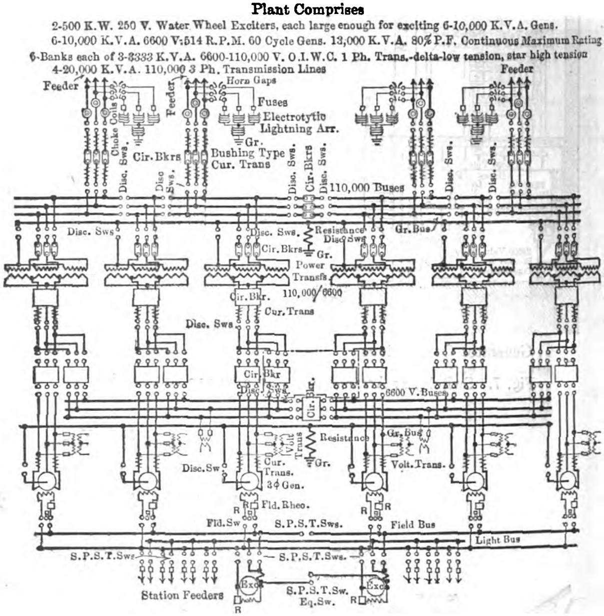

Fig. 9. Diagram of Connections for Plants

bus-bars. The low-tension neutral bus is provided with a grounding resistance and each generator is furnished with a single-pole, single-throw knife switch for connecting it to this grounding bus. In a similar manner the high-tension neutral bus is provided with a grounding resistance, and each bank of transformers is furnished with a single-pole, single-throw knife switch for connecting its neutral point to this ground bus.

Ventilation of Generators and Field Rheostats. — It should be noted that it is intended to locate directly opposite each machine a field-regulating panel containing electrically operated field rheostats and field switches, the grid resistances used with these electrically operated field rheostats being located just outside the building. Each generator will draw in air around the shaft and discharge it at the bottom of the stator to a short duct connecting with the tail race. With this arrangement of discharging the heated air from the generators into the tail race and locating the field rheostat resistors of the generators outside the building, the question of securing proper ventilation is greatly simplified. The generator building is separated from the transformer and switch house by about 20 feet in order to secure better lighting and better ventilation for both buildings.

Switching Gallery. — The control desk, instrument board, and exciter switchboard are placed on a gallery in such a manner that the station attendant

standing at the desk can readily observe the operation of the generator which he is controlling. The switching gallery is on a level with the basement floor of the transformer and switch house so that the switchboard attendant can readily pass into the basement of the switch house.

Switch House. — The basement of the switch house contains electrically operated oil circuit breakers, bus-bars, disconnecting switches, series and potential transformers for the 6600-volt generator and transformer circuits, as well as the oil and water piping for the various transformers. The 6600-volt circuit breakers and bus-bars are inclosed in masonry compartments, but the 110,000-volt circuit breakers and bus-bars are open, owing to the great difficulty and expense of installing masonry compartments for 110,000 circuits and the doubtful benefit to be obtained by such a course. On the main floor the transformers are arranged in one row and are mounted on cast-iron bases provided with wheels in such a manner that any transformer can be rolled out onto a low truck and then pulled outside the building, after the various water pipes, oil pipes, low-tension and high-tension connections have been opened.

ARRANGEMENT OF SWITCHGEAR FOR INDOOR STEP-DOWN TRANSFORMER STATIONS. — Fig. 10 shows the section of a transformer station for the control of two 44,000-volt, 3-phase incoming lines,

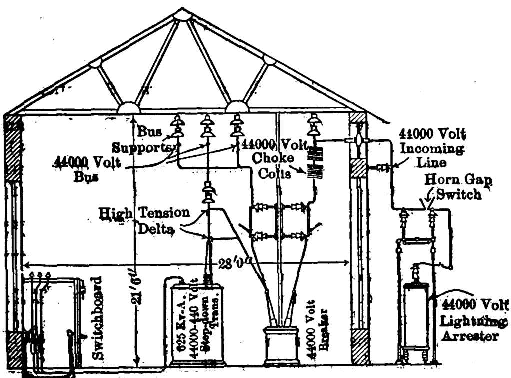

Fig. 10. 44,000-volt Step-down Transformer Substation

four banks each of three 625-kv-a. single-phase step-down transformers, and a number of 6600-volt feeder circuits. The 44,000-volt lightning arresters with their horn-gap disconnecting switches are placed out of doors, and the circuit breakers, transformers, disconnecting switches, and busses are located indoors as shown. The incoming leads pass through porcelain bushings in the walls to the choke coils and through disconnecting switches to the 44,000-volt breakers. From these breakers the current passes through other disconnecting switches to the 44,000-volt bus-bar that is hung from the ceiling by means of suspension insulators. From this bus the current passes through other disconnecting switches to the circuit breakers, and thence to the high-tension side of the step-down transformers.

As an example of a station designed for still higher voltages, Fig. 11 shows the arrangement of a plant for two 140,000-volt, 3-phase incoming lines, three banks of step-down transformers and the necessary switching equipment. In this

station the electrolytic lightning arresters are located on the roof of the station, and the disconnecting switches, circuit breakers, transformers, etc., are inside the station.

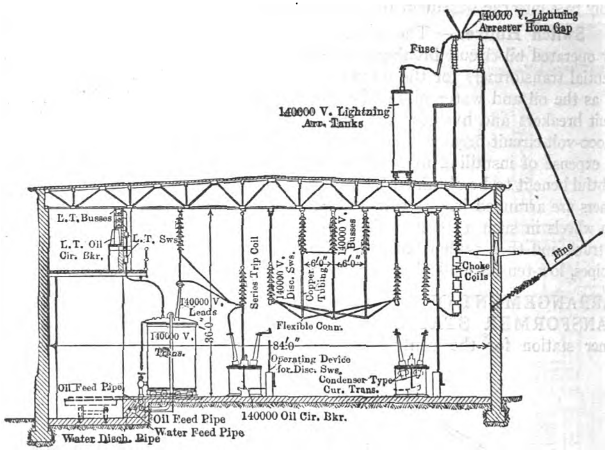

Fig. 11. 140,000-volt Step-down Transformer Substation

Comparison of Top- and Bottom-connected Breakers and Closed and Open Wiring (Fig. 12). — (*See also Bus-bars; Circuit Breakers.*) In order to illustrate the difference in the design of the station made necessary by the use of bottom-connected breakers and inclosed bus-bars for the high-tension circuits, Figs. 12A, 12B and 12C show three different designs of switching equipment for the control of 66,000-volt, 3-phase step-down transformers (each 10,000 kv-a.) supplying current to the two sets of 13,200-volt bus-bars.

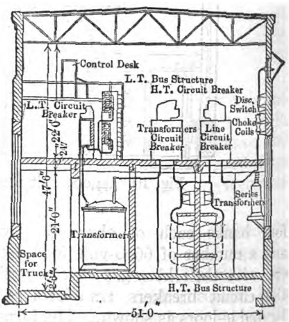

Fig. 12A. Bottom-connected Breakers, Inclosed H.T. Bus-bars, 66,000-volt Substation

Fig. 12A shows the general arrangement of the circuit breakers, bus-bars, connections, etc., using bottom-connected breakers of standard design and arranging to locate the 66,000-volt bus-bars with their disconnecting switches on the lower floor. In order to provide sufficient headroom for lifting the coils and iron out of a transformer case, it is necessary to slide the transformer into the passageway and run it along to the central portion of the building where the floor has been raised under the control desk in such a manner as to provide the necessary headroom. With this arrangement the total height of the building from the floor line to the roof girders is 47 feet 6 inches.

Fig. 12B shows the arrangement necessary if it is desired to use top-connected breakers and still inclose the 66,000-volt bus-bars. With this arrangement the 66,000-volt bus-bars, as well as the 13,200-volt circuit breakers with their

bus-bars, and the control desk, are placed on the upper floor, while the 66,000-volt breakers themselves with their disconnecting switches are located on the main floor near the transformers. With this arrangement any transformer can have its coils or iron removed as soon as it is slid into the passageway. The

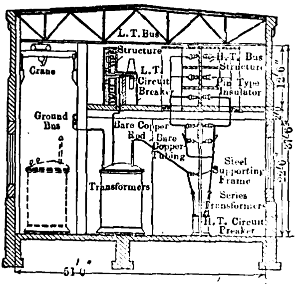

Fig. 12B. Top-connected Breakers, Inclosed H.T. Bus-bars, 66,000-volt Substation

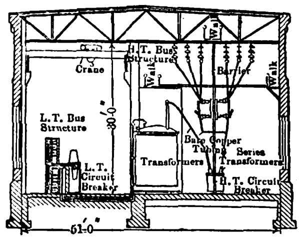

Fig. 12C. Top-connected Breakers, Open H.T. Bus-bars, 66,000-volt Substation

building arranged in this manner requires a height of 37 feet 6 inches from the floor line to the roof girders and requires a second floor the same as shown in Fig. 12A.

Fig. 12C shows the arrangement of this same station with top-connected breakers and open bus-bars and wiring for the 66,000-volt circuits. With this arrangement there is no necessity of a second floor. The height of the building is greatly reduced as the distance from the floor line to the bottom of the roof girders is only 30 feet.

ARRANGEMENT OF SWITCHGEAR FOR OUTDOOR TRANSFORMER STATIONS. — The use of outdoor transformers, switchgear and protective devices should be considered when designing high-voltage installations where it is essential to keep the first cost of the installation down to a minimum.

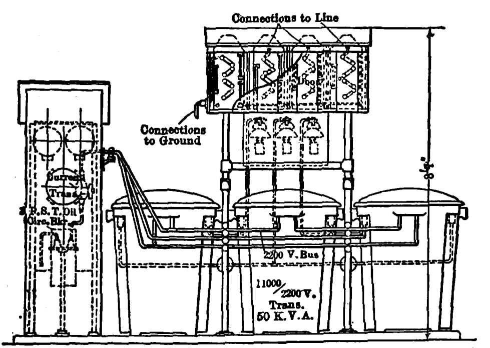

Fig. 13. Switchgear Arrangement for 110,000-volt, 150-kv-a. Outdoor Transformer Station

11,000-volt Station. — In Fig. 13 is shown an installation of three 50-kv-a., 11,000-volt, single-phase transformers with outdoor type expulsion fuse

switches and non-arcing lightning arresters. These arresters are placed in a wooden box with a swinging door. The low-tension switchboard is placed in a similar wooden box with a glass door so that the readings of the ammeter, voltmeter and watt-hour meter can be taken without opening the switch box.

33,000-volt Station. — A 33,000-volt installation with three single-phase self-cooling transformers is shown in Fig. 14. The layout also includes a three-pole, high-capacity, steel-tank, oil circuit breaker, a three-phase electrolytic lightning arrester and a small shed (not shown) containing the low-voltage switchboard.

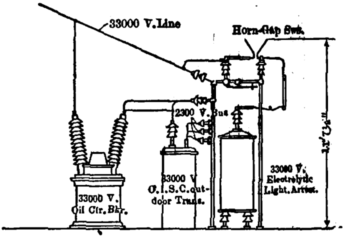

Fig. 14. Switchgear Arrangement for 33,000-volt, Outdoor Transformer Station

When installing these breakers all joints are painted with a heavy gum to safeguard against the entrance of moisture, and the breakers are painted regularly the same as any steel work exposed to the weather. Samples of oil are taken from the bottom and the top of the circuit-breaker tanks at regular intervals and if any evidence of an excessive amount of carbon in the oil is found the oil is immediately changed.

110,000-volt Station. — Fig. 15 shows a 110,000-volt installation with two incoming lines, two out-going lines, four banks each of three 3333-kv-a., oil-insulated, water-cooled transformers stepping down to 11,000 volts, with

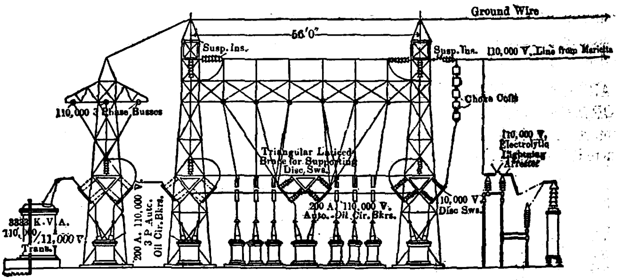

Fig. 15. Switchgear Arrangement for 110,000-volt, Outdoor Transformer Station

provision for two future 110,000-volt lines and additional banks of step-down transformers. The high-tension busses and the disconnecting switches are mounted on steel structures supported on transmission-line towers. The oil circuit breakers and transformers are located on the ground below the disconnecting switches. The transformers are mounted on wheels so that they can be run on a transfer truck and then hauled along a track until they are in the proper position to be pulled into the station for inspection and repair.

Owing to the number and the capacity of the low-tension circuit breakers needed for properly distributing the 11,000-volt current in an installation of this capacity, it is necessary to provide a small building (not shown) to contain the low-tension oil circuit breakers and the low-tension bus-bars. For this service, the circuit breakers and bus-bars have to be installed in masonry compartments owing to the enormous current available on the busses in case of short-circuit. The building also contains the small local-service transformers

with motor-generator sets, storage battery for the electrical operation of the main circuit breakers, and the switchboard on which the controlling devices for the various circuits are mounted.

Advantages and Disadvantages of Outdoor Stations. — The foregoing illustrations of outdoor stations indicate the tendency of design for such installations. The advantages of outdoor apparatus such as described are: (1) the cheapening of the installation due to saving in building, and (2) the reduction in life and fire hazard, owing to the fact that in an outdoor installation the apparatus can be well scattered without materially increasing the expense of the installation. The disadvantages are: (1) the absence of protection from the weather when inspecting, overhauling, or making repairs, and (2) the danger of trespassers to themselves and to the apparatus. The outdoor *apparatus* is somewhat more expensive than the corresponding indoor apparatus, but the difference in cost will be usually more than offset by the saving in *building* investment.

SWITCHGEAR EQUIPMENT FOR CONVERTING STATIONS IN BUILDINGS. — The proper grouping of the apparatus in a rotary-converter station depends on the voltage of the a-c. circuit, size of rotaries, type of transformers, and similar features. The building varies accordingly, provided the shape and size of the available lot is such as not to hamper the design of the station.

The sectional view of a rotary-converter substation containing 1000-kw., 6-phase rotaries with air-blast transformers fed from 13,200-volt, underground circuits is shown in Fig. 16. The incoming leads from the cable ducts pass

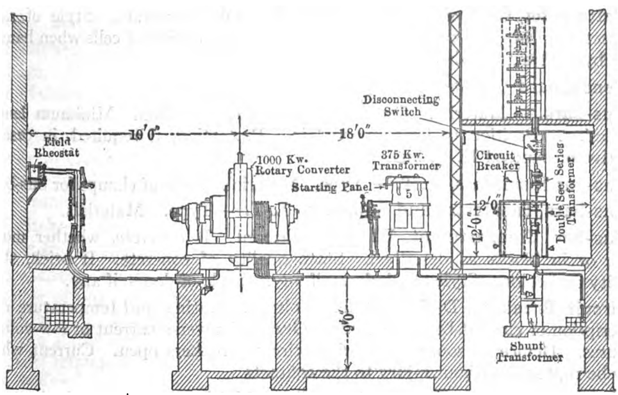

Fig. 16. Arrangement of Switchgear Equipment in Rotary Converter Station

through an oil breaker and disconnecting switches to the bus-bars that are located on a gallery. Provision is made for an additional set of bus-bars and an additional set of disconnecting switches to be installed at a later date so that any breaker may be connected to either of the two sets of busses.

The circuits from these bus-bars pass back through other disconnecting switches and breakers to the high-tension terminals located at the bottom of the air-blast transformers. The low-tension leads from the transformers go to a starting panel provided with double-throw switches that permit low voltages to be impressed on the rotary for the purpose of starting and full voltage for running. The rotaries are provided with series fields on the negative side.

The negative and equalizer switches are placed on a pedestal at the machine, and the negative and equalizer busses run on a bracket in the basement. The positive leads run to the panel board near the left-hand wall and the positive bus is located on the back of this board. The railway feeders are run out through underground ducts. All of the high-tension a-c. circuits are provided with electrically operated breakers controlled from the main switchboards. It will be noted that the entire design of this station hinges on the proper arrangement of the switching equipment.

SWITCHGEAR EQUIPMENT FOR PORTABLE CONVERTING STATIONS. — Many interurban electric railways have portable substations located in freight cars and arranged for ready transportation to whatever point requires their temporary service. A typical installation of this kind consists of a rotary converter; oil-insulated, self-cooling transformers; and the necessary panel switchboard, high-tension oil circuit breaker, and lightning-protective devices. The apparatus may be so arranged in the car that the operator is convenient to the handle of the high-tension oil breaker, the panel switchboard, and the commutator end of the rotary converter.

SPECIFICATIONS FOR SWITCHGEAR EQUIPMENT.* — The great variety of conditions to be met and the numerous ways of meeting each condition in switchboard work make it impossible to write specifications in the standard form suitable for general use. This specification is therefore in the form of a series of memoranda to assist in writing a more specific one. *(See also general article on Specifications.)* The items are arranged in alphabetical order.

Barriers. — Purpose. Material. Method of support. Dimensions.

Battery for Control. — Number of cells. Discharge rate. Style of rack. Protection of exposed copper from acid fumes. Condition of cells when handed over by contractor (whether charged or not).

Benchboard *(see Switchboard)*.

Bus-bars. — Material. Conductivity. Style of joints. Minimum length of section. Position to be supported in. Protection, if required, in case of positive or exposed H. T. bus.

Bus-bar Insulators, H. T. — Type. Material. Style of clamps for bus-bars.

Bus-bars, Insulators and Supports, L. T. — Type. Materials.

Bus-bar Compartment, H. T. — Material. If concrete, whether monolithic or in blocks as described. State quality of concrete. If brick, state quality and color. Style of windows, if any. Style of doors, if any.

Circuit Breakers, D-C. — Style. Voltage. Rating and temperature rise. Description of current-break features. Overload reverse-current or low-voltage features. Device to sound gong when circuit breakers open. Current which may be ruptured without injury to the contacts.

Conduits in Floors and Walls. — Size. Finish. Shall be laid when contractor is notified that floor is ready. Junction boxes, if any, shall have interiors of stated finish and shall be provided with a neat metal cover flush with the floor. Style of pipe joint to be such that any single length may be removed without disturbing others.

Crane Service Connection. — Apparatus required and location. Wiring.

False Floors. — Material of slabs. Description of slabs. Description of piers for supporting slabs. Style of fastening between slabs and piers.

Gongs. — Type and location. To what apparatus they are to be connected.

Ground Connections. — General description. Dimensions.

* By W. A. Del Mar.

High-potential Tests. — After installation, the apparatus and wiring shall be subjected to the potential tests specified in the following table, the tests being performed in accordance with the Standardization Rules of the American Institute of Electrical Engineers. (Give table of test voltages for different classes of apparatus and wiring, preferably from Section of the *Standardization Rules*, q.v.)

Instruments. — Type. Finish. Rating and description of scale. Accuracy at various parts of the scale to be within stated limits of accuracy. Location and style of terminals. Style, rating and temperature rises of shunts. Magnetic shielding.

Insulation (*see Insulating Materials*).

Lightning Arrester Equipment. — Type and purpose. Accessibility of all parts. Removability of all parts which may be injured by a stroke of lightning. Switches for disconnecting arresters from line. Description of ground plates and ground connections. Choke coils. Barriers.

Name Plates. — Description. Dimensions.

Relays. — Style. Location. Function.

Rotary-converter Starting Accessories. Method. Description of apparatus pertaining thereto.

Station Shunt. — Style. Location. Whether in positive or negative bus. Rating and temperature rise.

Switchboards. — Purpose. Material and color. General dimensions. Bench or upright. Number of sections per panel. Style of support. Sills, quality and finish (should not be painted if they are to be set in concrete). Size of bevel. Barriers: material, size and finish. Illumination.

Switches, H. T., Electrically Operated. — Style. Number of phases. Voltage. Rating and temperature rise. Accessibility of all parts. Description of concrete or brick compartment. Description of barriers between phases. Style of doors. Structure in base or elsewhere for disconnection switches. Voltage limits between which control apparatus shall operate successfully. Device to indicate positively at the controlling board whether the oil switch is open or closed. Device to sound gong when oil switch opens. Amount of oil to be supplied.

Switches, Oil, Hand-operated. — Style. Number of phases. Voltage. Rating and temperature rise. Location.

Switches, Knife or Toggle, Hand-operated. — Style and material. Number of poles and throws. Voltage. Rating and temperature rise. Quick break features, if required. Current density in metal and at contacts shall not exceed a stated value. With or without base, and style of base, if any. Front or rear terminals. Style of terminals. Long-handled hooks for h.t. knife switches.

Switches and Circuit Breakers, L.T., Electrically Operated. — Circuit breakers (*see also Circuit Breakers, D.C.*). Switches (*see also Switches, H.T.*). Device to indicate positively at control board whether switch is open or closed. Voltage limits between which control apparatus will operate sucessfully.

Transformers for Instruments. — Style. Ratio. Rating and temperature rises. Maximum permissible percentage error in ratio.

Wiring, Power Circuits. — Use. Location. Shall be clamped so that wires will not be dislodged should any joint or terminal become loose. Description of protection where cables pass through floors or walls. Tagging with number of circuit. Conductivity. Size or carrying capacity. Conductivity of clamps or terminals. Style of insulation.

TOTAL COST OF SWITCHGEAR EQUIPMENT

These costs should be used with caution; *see paragraph on Costs in text, p. 1503.*

No.	Type of station	Breaker equipment	Volts	Number of Gen.	Number of Feed.	Number of Trans.	Number of Lines	Price
1	Generating	Hand operated, moderate capacity	2,300	1	..	..	..	$450
2	Generating	Sol. operated, small capacity	2,300	1	..	..	..	525
3	Generating	Sol. operated, moderate capacity	6,600	1	..	..	..	825

Wiring for Control and Instruments. — Use. Location. Accordance with city ordinances and rules of "National Board of Fire Underwriters." Ends of each conductor shall be tagged with numbered tags of stated material and design fastened with brass wire. Wires which it is inadvisable to keep together shall be in different pipes as directed by the Engineer. Conductivity. Size. Style of insulation.

COSTS. — It is impossible to give reasonably accurate figures upon the cost per kv-a. of switch-gear equipment because of the large number of independent factors entering each case, such as type of station, voltages, number of generators, feeders, transformers and lines, single-throw or double-throw switching arrangements, etc. The figures in the preceding table may be used as a basis for approximate preliminary estimates, the prices including all switches, circuit breakers, bus-bars, structures, cables, wiring, lightning arresters, panel boards, control desks, instrument transformers and including erection and installation with all main wiring between apparatus and switching equipment.

SYNCHRONIZERS AND SYNCHROSCOPES. — (*See also Alternating Currents; Converters, Synchronous; Generators, Alternating-Current; Power Stations; Substations; Switchgear Equipment for Power Stations.*) The two principal functions of any synchronizing device are to indicate (1) when the two circuits to which it is connected are operating at the same frequency, and (2) when the voltages of the two circuits are in phase with each other. The voltages of the two circuits must also be equal in effective value; this is usually determined by means of voltmeters connected to the two circuits. The process of synchronizing is simplified if the synchronizer indicates whether the machine to be synchronized is operating at a frequency lower or higher than that of the system to which it is to be connected.

The name "synchroscope" is usually applied to any device which, in addition to indicating synchronism, shows whether the machine to be synchronized is fast or slow (*see Standardization Rules of the A.I.E.E.*). The name "synchronizer" is used in a broader sense for any kind of synchronizing device.

Synchronizing Lamps. — The simplest form of synchronizer consists of two incandescent lamps shunted around the main switch which connects the machine to the bus-bars; see Fig. 9A, p. 648. Equality in frequency, voltage and phase between the bus-bars and the machine to be synchronized is then indicated by continued darkness of the lamps. For three-phase circuits a similar arrangement may be used, if the lamps are connected between corresponding phases of the two machines which are to be brought into synchronism with each other. If the machines are not in synchronism the frequency of pulsations of brightness of the lamps will be proportional to the difference of the frequencies of the two machines. The lamps do not show whether the machine is running too fast or too slow, nor is the point of exact synchronism very definitely indicated, as it requires an appreciable potential to cause the lamps to glow. The latter difficulty may be avoided in the case of single-phase machines by employing the connections shown in Fig. 9B, p. 648; when the lamps are thus connected they indicate synchronism when at maximum brightness.

Use of Transformers with Synchronizing Lamps. — Transformers are frequently used in connection with the lamp. The arrangement with two transformers is to have the primary of one connected across the terminals of the machine, and the primary of the other connected across the bus. The secondary windings are connected in series with the lamp. The secondary connections may be arranged so as to have either darkness or maximum brightness at the instant of zero phase displacement between the bus-bar voltage and the voltage of the machine. Instead of using two separate transformers a single transformer with two primary windings and one secondary winding may be used; such a transformer is called a "synchronizing transformer." The primary windings are usually connected to give full voltage across the lamps at synchronism.

Siemens and Halske Three-phase Synchronizing Lamps. — Three similar lamps L_1, L_2 and L_3 are connected between the three terminals A_1, A_2 and A_3 of the machine and the bus-bars B_1, B_2 and B_3. Lamp L_1 is connected between corresponding phases, that is, between A_1 and B_1. Lamp L_2 is connected between A_2 and B_3 and lamp L_3 is connected between A_3 and B_2. Synchronism will be reached when L_1 remains dark; L_2 and L_3 will then be equally bright. If the machine falls out of step, the lamps will successively grow bright and dark in rotation, no two lamps being in darkness or at maximum brightness at the same time, i.e., the light will appear to travel from one lamp to another at a definite speed and in a definite direction. The speed of rotation of the light is proportional to the difference of frequency between the voltage of the bus-bars

and that of the machine. The direction in which the light appears to travel indicates whether the frequency of the machine is greater or less than that of the bus-bars. For high-tension circuits, potential transformers are required.

Dial Synchroscopes. — Dial synchroscopes are similar in construction to power-factor indicators (q.v.), but are connected between the two circuits which are to be brought into synchronism. They are designed to indicate by a movable pointer whether the machine to be synchronized is running too fast or too slow, or whether it is in synchronism with the circuit to which it is to be connected.

Moving Coil Type. — A fixed coil is connected through a resistor across the bus; in polyphase circuits across one phase. The movable coil is connected through a condenser to the terminals of the machine to be synchronized, and is normally held in a position at right angles to the fixed coil by means of a spring. There will be no torque acting on the movable coil when the machine and bus voltages are either exactly in phase or 180° out of phase with respect to each other, because in either case the currents in the fixed and movable coils are in quadrature. When the two circuits are not in synchronism, the pointer attached to the movable element will swing back and forth over the scale. In order to distinguish the point of synchronism from that of 180° phase displacement, a translucent glass scale is placed in front of the pointer, the scale being illuminated by a lamp connected to the low-tension side of a "synchronizing transformer" which causes the lamp to be lighted when coincidence of phase between machine and bus occurs. Hence the pointer is visible only during every other swing, i.e., it will appear to rotate in one direction; the direction of rotation indicates whether the machine is fast or slow.

This instrument is applicable to single-phase as well as polyphase circuits, as it is usually unnecessary to indicate synchronism of more than one phase on any machine. The moving-coil synchroscope is ordinarily used with transformers, stepping the line voltage down to 110 volts.

Rotating Iron-vane Type. — This instrument is similar to the moving-vane type of power-factor meter (q.v.). The movable iron vane is magnetized by a stationary coil connected across the machine to be synchronized. A rotating field is produced by passing current from the bus-bars through a split-phase winding and two fixed coils placed nearly 90° apart. The pointer indicates at any instant the phase displacement between the voltages of bus-bars and machine. The speed and direction of its rotation depends on the difference in frequency of the two circuits. When exact synchronism is reached the pointer will remain at rest in a vertical position. The instrument is usually connected through potential transformers; on polyphase circuits only one phase is used.

Lincoln Synchroscope. — This instrument has a rotating iron core carrying two coils placed nearly 90° apart; one coil is connected through a resistance, and the other through an inductance, both being supplied from the machine to be synchronized. A bipolar, laminated iron field is magnetized by means of a coil connected to the bus-bars. The operation of this instrument is similar to that of the moving-coil type of single-phase power-factor meter. A pointer attached to the moving system indicates at every instant the difference of phase angle, as well as the approximate difference of frequency, between the voltage of the bus-bars and that of the machine to be synchronized. The current has to be led into the armature coils through slip rings as the armature is free to revolve. These instruments are furnished for direct connection to circuits of 110 or 220 volts; other circuits require transformers.

Automatic Synchronizers. — These are designed for the purpose of entirely eliminating the judgment of the switchboard operator as to the selection of the proper instant for closing the switch connecting the incoming machine to the bus. Automatic synchronizers are particularly desirable when remote-control

oil switches with appreciable time elements are used; see *Circuit Breakers.* The voltage and speed of the incoming machine must be regulated by the attendant. The principal parts of the automatic synchronizer are two solenoids and a movable contact-making sector which is operated by the joint action of the cores of the two solenoids. There are two equal windings A_1 and A_2 on solenoid A and two windings B_1 and B_2 on solenoid B. The windings A_1 and B_1 are connected in series, and A_2 and B_2 are connected in series. The first circuit is connected across the bus and the second across the machine through suitable potential transformers. Connections are such that when the two potentials are of equal value and have the same frequency and phase, the pull on one core will be zero and that on the other will be a maximum. The cores of the solenoids are connected at the top through a centrally-pivoted lever to which the contact-making sector is connected.

At exact synchronism the pull on the core of A is zero and that on the core of B is a maximum; at 180° phase displacement the pull on the core of A is a maximum and that on the core of B is zero; when the voltages are in quadrature the two cores receive equal pulls. The sector will oscillate back and forth when there is a difference of frequency, the oscillations being similar to the pulsations of the synchronizing lamp. When B is fully drawn in, i.e., for equality and zero phase difference of the two voltages, the sector closes the contacts which close the energizing circuit of the relay switch. The latter closes the circuit for operating the main oil switch. The relay switch is usually necessary, as the current required to operate the main oil switch is greater than the current-carrying capacity of the two synchronizer contacts. Provision is also made for introducing a time element such as to prevent coupling the machine to the bus when the voltages are only temporarily in phase. Adjustments may be performed for varying this time element in accordance with the time element of the main oil switch, and for varying the maximum allowable voltage difference and frequency difference at the instant of connecting the machine to the bus.

Complete equipment for automatic synchronizing includes (1) the automatic synchronizer; (2) a relay switch, mentioned above; (3) one control switch per generator, by which the main switch may be opened but not closed; (4) one potential transformer per generator; (5) one potential transformer for the bus-bars. The potential transformers used in connection with the station meters may be used with the automatic synchronizer. It is preferable to have a set of synchronizing lamps in addition to the above equipment, as the automatic synchronizer gives no direct indication of the frequency and phase of the incoming machine. Automatic synchronizers can be used only in connection with electrically-operated switches or circuit breakers, the auxiliary circuits being supplied from an exciter bus or some other independent source.

COSTS. — A moving-coil synchroscope costs approximately $55; a 9-inch moving-vane synchroscope costs approximately $45; a Lincoln synchroscope for voltages of from 110 to 220 costs from $45 to $55; transformers and accessories are extra in all cases. An automatic synchronizer exclusive of auxiliary equipment costs approximately $125; the auxiliary equipment comprising one relay switch, one control switch, and two potential transformers for 6600-volt circuits at 60 cycles per second costs approximately $85, exclusive of the electrically-operated switch. Only one synchroscope or synchronizer is required in a station, although a spare instrument is usually installed.

TELEGRAPH INSTRUMENTS AND APPARATUS. — (*See also Telegraph Lines; Telegraph Systems; Wireless Telegraphy.*) The more important instruments and apparatus used in the various systems of telegraphy are described below.

KEYS. — A telegraph key is essentially a switch for opening and closing a circuit. Various types of keys are in use.

Standard Morse Key (Fig. 1). — The knob end of the lever is normally held raised so as to open the key by an adjustable coiled spring. The auxiliary switch arm constitutes the "circuit closer" by which the circuit of the line is kept closed, through the key, while the key is not in use.

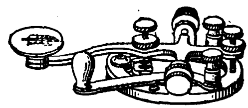

Fig. 1. Standard Morse Key

Double-acting Key. — While the key of the general type illustrated in Fig. 1 is still standard, several later forms, having a sidewise rather than an up and down motion of the lever, have come into some vogue. One type of these, known as the double-acting key, has its operating lever arranged to swing in a horizontal arc between two stationary contact points. The key lever normally stands clear of both points, leaving the circuit open. A movement either to the right or left will close the circuit.

Vibroplex. — Another type of key is represented by such instruments as the Vibroplex, which are more properly semi-automatic transmitters. The motion of the key lever in this is similar to that of the double-acting key just described, the lever normally standing in the middle or open position. When the key is pushed to the left, it closes the circuit in the ordinary way to make a dash. When pushed to the right, a vibratory reed is set in motion, which opens and closes the circuit rapidly to form a succession of dots, the number of dots being controlled by the length of time the key is held in this position. By this means the operator is relieved of the muscular effort of rapidly vibrating the key to form dots.

Operator's Paralysis. — The objects of the double-acting key and of the Vibroplex and other similar transmitters are, in the main, twofold: To relieve or prevent the malady known as "operator's paralysis" or "loss of grip," which sometimes follows long continued use of the ordinary key; and to increase the speed of transmission.

AUTOMATIC TRANSMITTERS. — (*See also Telegraph Systems.*) The transmitters in automatic systems usually employ a paper tape, perforated in accordance with the code to be sent. This tape, so prepared, is caused, by means of revolving rollers, to pass rapidly through the transmitter, the perforations serving as they pass to permit electrical contacts to be made which send the proper impulses to the line.

SOUNDERS (Fig. 2). — A standard form of sounder is shown in Fig. 2. The winding of the electromagnet is connected directly between the binding posts shown on the base of the instruments. The armature is attached to a lever mounted on trunnions in a fixed support. The adjustable stops provided for the lever permit a slight up and down movement of its free end, the downward movement being caused by the pull of the electromagnet, and the upward one by the force of an adjustable retractile spring. The rugged construction of the armature lever and its co-operating parts is required to produce the necessary loudness and quality of sound.

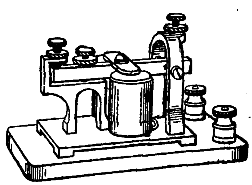

Fig. 2. Morse Sounder

This, with the heavy retractile spring necessary for the prompt return movement of the lever, makes the instrument require more energy for its operation than can usually be delivered to it directly over the line wire. On this account the sounder magnet is usually placed in a local circuit, which is in turn controlled by the more sensitive relay, the magnet of which is placed directly in the line.

When used in local circuits sounders usually have a magnet resistance of about 4 ohms, and require about ¼ ampere for their proper operation. Where the sounder magnet is placed directly in the line, it is termed a main line sounder, and differs in no respect from the local sounder except that its magnet is wound to about 20 ohms.

RELAYS. — Two kinds of telegraph relays are employed; the ordinary or Morse relay, and the polarized relay. The armature of a Morse relay always moves in the same direction irrespective of the direction of the current impulse, while the armature of a polarized relay moves in one direction for a positive impulse, and in the opposite direction for a negative impulse.

Morse Relay (Fig. 3). — The Morse relay has the same essential parts as the sounder, with the addition of a pair of contacts closed by the armature lever when in its attracted position. The armature lever is usually mounted vertically, and is made light in construction so as to be capable of the necessary rapid to and fro movements with a minimum expenditure of energy. The retractile spring is light and delicately adjustable. An extra pair of binding posts is added to form the terminals of the local circuit, these binding posts being wired to the armature and the magnet frame, respectively, so that the circuit between them will be closed upon the attraction of the armature. The back contact of the relay is non-conducting, so as to avoid closing the circuit when the armature is released. A typical form of relay, known as the "pony relay," is shown in Fig. 3.

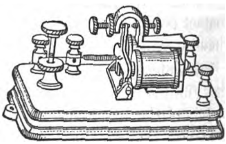

Fig. 3. Morse Relay

Polarized Relay. — A polarized relay is similar to a Morse relay except that the end of the armature which plays between the soft-iron pole pieces is permanently magnetized. For example, if this end of the armature is a north magnetic pole, then, obviously, the armature will be moved in one direction or the other, according as the magnetizing force of the coil tends to set up a south pole in one or the other of the poles. The polarity of the poles, of course, changes with the direction of the current in the coil.

RECORDERS OR REGISTERS. — (*See also Telegraph Systems.*) Recorders or registers are used only where for some reason it is desired automatically to record a message. Simple forms of comparatively slow speed registers are used in connection with district telegraph messenger and fire alarm telegraph service. More elaborate high speed recorders are used in connection with automatic and printing systems. A special form of recorder, known as a siphon recorder, is used on submarine lines.

Slow Speed Registers. — The paper upon which the message is to be recorded is a narrow strip of tape, carried on a reel. A clock-work motor is provided for moving the tape at uniform rate under the recording pen or stylus. The receiving magnet of the register is placed in a local circuit controlled by a relay in the line, and this magnet, when attracted, serves either to move the pen or stylus against the tape or the tape against the pen or stylus, in either case resulting in a mark upon the tape. Some registers record by merely embossing the tape; others by marking thereon with a pen or pencil; and still others by actually punching holes in the tape.

High Speed Recorders. — In very high speed automatic and printing systems receiving devices have been developed giving a record in ink on ordinary paper, or a record on a sensitized paper, or in ordinary print. For a description of the more important printing recorders see below under *Telegraph Systems*.

Chemical Recorders.—For very high speed work with non-printing telegraphs the chemical recorder has been generally found the most satisfactory. In this the tape is impregnated with a solution of some unstable chemical compound which will easily be decomposed upon the passage through it of an electric current, and which, either by changes within itself or by combination with the material of the pen through which the current passes, will cause a definite discoloration of the tape upon the passage of the current.

A common sensitizing solution is formed of 5 parts of prussiate of potash, 150 parts of ammonic nitrate, and 10 parts of water. Under electric decomposition, this solution sets free an acid which attacks the iron of the pen, leaving a blue mark on the paper.

Siphon Recorder. — The high electrostatic capacity of long submarine cables makes necessary some modification of the methods ordinarily employed in overland work. This high capacity results in the variations in the signaling current being less sharply defined than on land lines. The receiving apparatus for long cables must, therefore, be responsive to minute variations in current to such an extent as to preclude the use of the responsive devices employed on land lines.

The siphon recorder is merely a special form of recording galvanometer. The galvanometer proper is of the D'Arsonval or swinging coil type. The motion of the coil is imparted to a very light glass tube bent to form a siphon and suspended with its long end opposite the receiving tape and its short end dipping into a small tank of ink. The siphon moves across the width of the tape, the contact with the tape being agitated so as to be nearly frictionless. Displacements in this record line to the left of an imaginary zero line represent dots, those to the right, dashes. The Continental code is universally employed when a siphon recorder is used.

TELEGRAPH REPEATERS. — When, for any reason, it is desired to transmit messages from one line to another line without manual retransmission, the telegraph repeater is used. By its use lines of excessive length may be avoided, and a consequent increase of speed may be attained. Again, the repeater is often useful in automatically transmitting messages from a through circuit to a side circuit.

Non-Automatic or "Button" Repeater (Figs. 4 and 5). — A fundamental conception of the repeater may be gained from Fig. 4, where a relay magnet

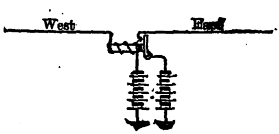

Fig. 4.

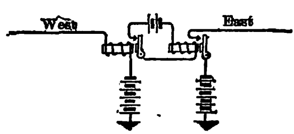

Fig. 5.

placed in one line causes an armature to act as a key to make and break the other line. This conception may be carried a step farther by considering Fig. 5, where a relay magnet in the West line receives impulses from the distant West station, and controls a local circuit containing a battery and a second relay magnet, which latter causes its armature to act as a key in transmitting signals

to the East line. From these two figures it is obvious that such a repeating scheme would transmit in one direction only, providing no facilities for transmitting from East to West.

The "button repeater" of early telegraph history consisted practically of two such sets of relays as are shown in Fig. 5, these sets being arranged for transmission in opposite directions. Only one set of relays could be kept connected to the line, for when both are connected in, the impulses sent out from the repeating station on, say, the West line react on the line relay of that line at the repeating station in such way as to act through its local circuit to send impulses back on the East line. This difficulty was overcome in the button repeater by providing a button switch, operated by an attendant at the repeater station, this switch being thrown manually in one direction or the other, according to the direction of transmission desired.

Automatic Repeaters. — The necessity of an attendant for the purpose of working the switch of a repeater has long since been overcome by the production of the so-called *automatic repeaters*, of which there are many forms. In these, the arrangement is such as to automatically prevent the transmitter of the line *that is being repeated into from reacting to make and break the line over* which the signals are initially sent.

The Milliken Repeater (Fig. 6).— This is one of the most common of the automatic repeaters for the simple Morse system. Its action may be

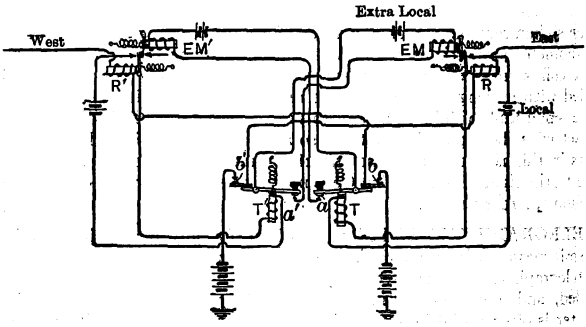

Fig. 6. Milliken Repeater

understood by reference to Fig. 6. If the line East is sending, the relay *R* will respond to the make and break impulses of the key at the distant station on that line, this line being closed to ground and battery at the repeater station through the contacts *b′* on transmitter *T′*, which is held closed by an action that will be described. The operation of the relay *R* of the line East will, by its local circuit, cause the corresponding operation of the transmitter *T*, and this, by the make and break at the tongue *b*, will open and close the line West in accordance with the originally transmitted impulses. The armature of the relay *R* will be free to work, because as long as the magnet of transmitter *T′* remains energized it will hold the circuit of the extra magnet *EM* closed at the point *a′*, and thus will hold the armature of that magnet out of the way of the armature of the relay *R*. The extra magnet *EM′*, associated with the relay *R′* of the line West, prevents this relay from breaking the West line in response to the repeated signals, for the following reason. When the line West is closed by the transmitter *T*, the current through the relay *R′* holds its armature attracted. When

the line West is opened, however, by the transmitter T, the circuit of the extra magnet EM' is also opened by this transmitter, and the retractile spring of the extra magnet prevents the armature of the relay R' from falling back. In this way the line relay of the West line cannot react on its own transmitter to cause makes and breaks in the transmitting line. When the operator at the distant station on the West line breaks, the relay R' is then permitted to open and thus cause the transmitter T' to open the line East.

Duplex and Quadruplex Repeaters.—Automatic repeaters are more simple for duplex and quadruplex systems than those already described for "single" wire working. The reason for this is that in the duplex or quadruplex the transmission from a given sending operator is always to a corresponding receiving operator, and — as between these operators — it is never in the reverse direction. Hence, a one-way repeater only is required for any one of the several simultaneous transmissions. It therefore suffices to place the transmitter at the repeating station under the control of the neutral or polar relays of the duplex or quadruplex, the repeating operation for each set being in one direction only.

CURRENT SUPPLY.—Either a battery or a dynamo may be used to supply the current required for telegraph transmission.

Gravity Battery.—The gravity battery was once almost universally used for supplying current in telegraph systems. It is still largely used on unimportant lines and in small offices where it is not economical to employ machine generators or secondary batteries.

Storage Battery.—The storage battery, on account of its extremely low internal resistance, is capable of handling any desired number of lines in parallel, and this led to the use of the so-called "universal battery system," in which a single battery, with one pole grounded, serves the line wires which are tapped off from the other pole. Suitable resistances were included in the lines of lower resistance, if desired, to compensate for the variation in resistance among the lines. One battery, thus used, would not suffice for an office, however, since with the various systems of duplex and quadruplex working it is necessary to send currents of alternate polarity to line, thus making necessary the use of another battery with its opposite pole grounded. Usually also a reserve was provided for each of these batteries, so that one could be used while another was being charged.

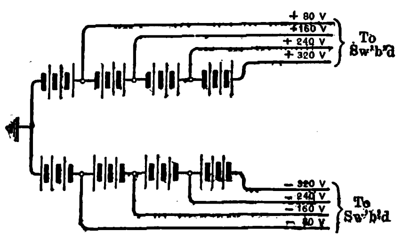

Fig. 7. Storage Battery for Current Supply

In Fig. 7 is shown an arrangement of storage battery supply that provides for any gradation of voltage of either polarity in an obvious manner. By using a duplicate of this arrangement, one set may be charged while the other is being used.

The Dynamo.—The dynamo has generally supplanted both the primary and secondary batteries in all offices large enough to warrant its use. In Fig. 8 a dynamo arrangement employed by the Western Union Telegraph Company is shown. In this five machines constitute a set, their armatures being connected in series, taps being made as indicated to give the required voltages. All of these machines are separately excited except the fifth, which

latter is a shunt machine and furnishes current not only for line supply but also for exciting the fields of all the other machines. Each field circuit is provided with a separate rheostat *R* for varying the field strength. Another set like this is employed to furnish currents of the opposite polarity, and still another set of five machines is employed as a reserve, this being so arranged that

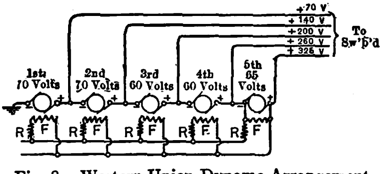

Fig. 8. Western Union Dynamo Arrangement

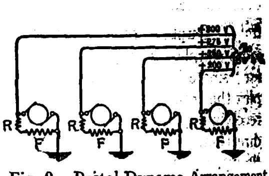

Fig. 9. Postal Dynamo Arrangement

it may be made to generate either positive or negative according to which of the regular sets it is to replace. The dynamo arrangement employed by the Postal Telegraph-Cable Company is shown in Fig. 9.

TELEGRAPH SWITCHBOARDS (Fig. 10).—Telegraph switchboards were the precursors of the vastly more complicated telephone switchboards. The telegraph switchboards which have been most commonly used in America are of two types—the "strap and disc" and the "cross-bar."

A simple "strap and disc switchboard" with its connections is shown in Fig. 10. The lines terminate in the vertical straps and the instrument circuits, each including key and relay, terminate in the horizontal rows of discs, the discs in each row being connected together, as indicated by the dotted line. This figure also shows a typical method of line and instrument protection.

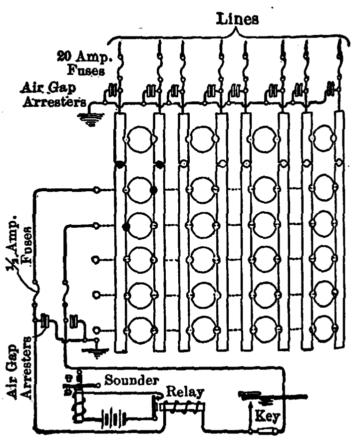

Fig. 10. Strap and Disc Switchboard

COSTS.—The following prices were current in 1913: standard Morse key, $2.20; double-acting key, $10.00; Vibroplex, $12.00; standard Morse sounder, $3.00; standard Morse relay, $7.00; polarized relay, $20.00; ink recorder, $35.00; punching recorder, $75.00. See also *Batteries, Generators,* etc.

BIBLIOGRAPHY.—See Bibliography in article on *Telegraph Systems.*

[S. G. McMeen.]

TELEGRAPH LINES. — (*See also Poles and Cross-Arms; Telephone Lines; Transmission Lines; Wires and Cables.*) The conductor over which transmission is effected is commonly referred to as the line. These conductors may exist as open wires, or they may be disposed in aerial, underground and submarine cables.

OPEN-WIRE LINES. — Most of the open-wire telegraph lines are of hard-drawn copper or of galvanized iron. Recently a wire known as copper-clad steel, consisting of a core of steel wire with an outer shell of copper welded thereto, has appeared as a serious competitor. For the properties of these wires see *Wires and Cables, Bare*.

Hard-drawn copper wire is vastly superior to iron in point of conductivity and in its ability to withstand the action of the elements. Galvanized-iron wire is advantageous in point of first cost, it has a somewhat greater strength, but has a life ranging from 4 to 20 years, according to atmospheric conditions. Copper-clad steel has a conductivity superior to that of iron, but inferior to that of copper. It is stronger and somewhat cheaper than hard-drawn copper, and should possess the same ability as copper to indefinitely withstand the action of the elements.

The mile-ohm values (i.e., the weight in pounds of a wire one mile long having a resistance of one ohm) of the various grades of wire used for telegraphic purposes are as follows: E.B.B. iron, 4700 pounds; B.B. iron, 5500 pounds; steel, 6500 pounds; hard-drawn copper, 895 pounds; copper-clad steel (having conductivity 40 per cent of solid copper), 2010 pounds.

No. 9 B. & S. gauge hard-drawn copper wire, weighing 209 pounds per mile, is more used than any other size of hard-drawn copper wire for telegraphic purposes; and No. 8 B. W. G. galvanized-iron wire, B.B. grade, weighing 378 pounds per mile, is the principal standard in iron wire.

AERIAL CABLES. — The paper-insulated, lead-covered cable of the type employed in telephony (*see Telephone Lines*) but with single wires instead of twisted pairs, is rapidly supplanting the old form of rubber-insulated cable formerly used in telegraphy. Sometimes the cores are saturated with insulating compound, and sometimes they are left "dry," according to whether the consideration for greater safety outweighs the desirability for lower capacity. For aerial work such cables are supported from messenger wires, either by means of clips or by a wrapping of marline around both the cable and the messenger, this form of support being applied by means of the well-known "Spinning Jenny."

UNDERGROUND CABLES. — (*See also Wires and Cables, Insulated.*) Underground telegraph cables are of the same type as those used for aerial. The practice of placing them in ducts extending from manhole to manhole, so as to facilitate their withdrawal, has largely replaced the older practice of burying the cable in such manner as to necessitate its being dug up for replacement or repairs.

SUBMARINE CABLES. — For comparatively short lengths, in crossing rivers or bays where the current is not swift and the bottom is of such a nature as to naturally embed the cable, ordinary multiple-conductor, lead-covered cables, with either paper or rubber insulation, provided with a heavy braiding, are often employed. Where paper insulation is used, it is customary in telegraphic work to thoroughly impregnate the core so as to minimize the bad effect of moisture; but this, of course, increases the electrostatic capacity of the conductors.

Where great tensile stresses or abrasion are likely to occur, the core, after being provided with its lead sheath, is served with a thick cushoning layer of tarred jute, and then with an armor of closely wrapped galvanized-steel wires, over which an additional protecting layer of tarred jute is sometimes placed.

Long Submarine Cables. — For long submarine cables, such as those across the Atlantic Ocean, a single conductor is employed, this being in the form of stranded copper, weighing from 70 to 650 pounds per nautical mile. This conductor is then encased in several layers of gutta-percha. The insulated core, so formed, is protected with a thick layer of jute, outside of which the armoring of galvanized-steel wires is placed. After being sheathed, the whole cable is sometimes covered with a thick layer of tarred tape. The shore ends of cables, where there is greater liability to mechanical injury, are armored with a layer of very heavy galvanized-steel wires.

LIMITING TRANSMISSION DISTANCE. — The length of the line over which a signal can be transmitted depends upon the strength of the current impulses sent out, the sensitiveness of the receiving instruments, the resistance and capacity of the line and upon the number of stations connected to the line.

Open Wire Lines. — The following table, compiled by Mr. F. F. Fowle, shows the result of his calculations as to the limiting lengths for through working (no intermediate stations) of simplex, duplex and quadruplex Morse transmission with standard apparatus over open wire lines with ground return having different resistances per mile, and also the maximum line distances for way circuits equipped with 35-ohm line relays.

Resistance per mile in ohms	Limiting length of line for Through Working, miles			Limiting length of Way Circuits, miles		
	Duplex	Simplex	Quadruplex	A*	B*	C*
2	783	597	531	597	391	313
3	658	510	442	510	363	299

CONSTRUCTION OF LINES. — (*See Telephone Lines.*)

BIBLIOGRAPHY. — See Bibliography in article on *Telegraph Systems*.

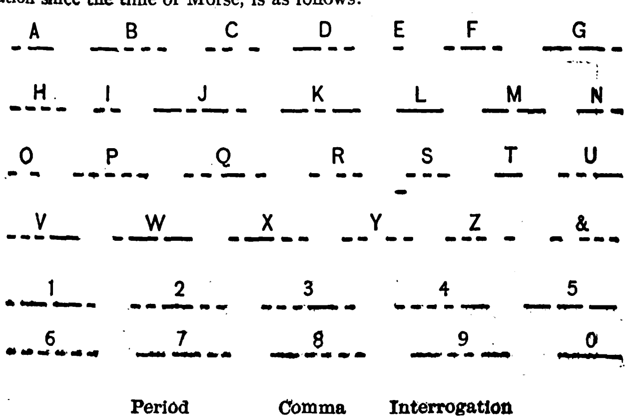
[S. G. McMEEN.]

TELEGRAPH SYSTEMS. — (*See also Telegraph Instruments and Apparatus; Telegraph Lines.*) The following is a brief table of contents of this article:

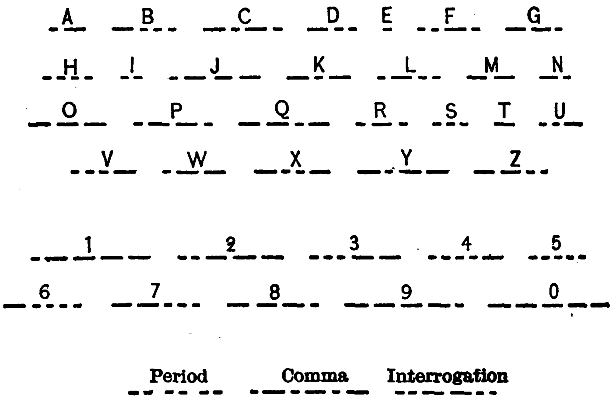
With slight modification the original system of electric telegraphy devised by Morse is still largely used, the great bulk of telegraph work still being done by it. In its simplest form it consists of a circuit, connecting the points between which intelligence is to be transmitted, a battery or other generator in the circuit for supplying the current, a key at each station for facilitating the opening and closing of the circuit by hand, and a sounder for giving response to the opening and closing of the circuit by audible clicking.

TELEGRAPH CODES. — Two different codes are used in telegraphy, the Morse code and the Continental code.

Morse Code. — The Morse code is an arbitrary system of interpreting the various letters, numeral digits and punctuation marks employed in writing, this interpretation being intelligible either audibly or visually. This code is formed of dots, dashes and spaces. The dot is made by a quick depression of the key followed by its immediate release; the dash by a depression of the key with a delayed release; and the space by permitting a short interval to elapse between the completion of two dots. Thus, the letter *a* is represented by a dot and a dash, and it is formed by depressing the key, immediately releasing it, depressing the key again and holding it a slight interval before release. Similarly, the letter *i* is represented by two dots, and it is formed by depressing and releasing the key twice in rapid succession. The letter *o* is an example of a so-called space letter, and is represented by dot-space-dot. It differs from the letter *i* only in that an interval of time is allowed to elapse between the two dots. The Morse code, as it has been employed practically without modification since the time of Morse, is as follows:



Continental Code. — The so-called Continental Code differs from the Morse code in that it is composed entirely of dots and dashes, employing no spaces. It is almost universally used for submarine lines, and for land lines in nearly all countries except the United States. This Continental or universal code is as follows:



SIMPLEX OR MORSE SYSTEM. — There are two types of circuits used, the so-called "open-circuit" system and the "closed-circuit" system. In both cases but one line wire is employed, the earth forming the return circuit.

Closed-circuit System (Fig. 1 and 2). — This system is mainly used in the United States. In its simplest form the keys and the sounder magnets are placed in series in the line with a source of current, as shown in Fig. 1. A

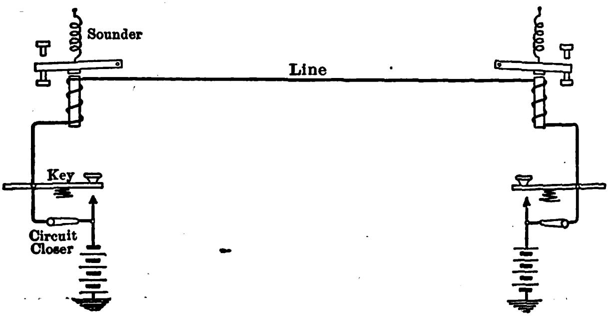


Fig. 1. Simple Telegraph Circuit

switch or "circuit closer" is provided with each key, the function of which is to keep the line circuit closed around the key contacts when the key is not in use. When an operator begins to send he opens this circuit closer, thus making his key effective in controlling the line circuit. When the line is idle, the circuit is closed at all stations, and all sounder levers are held down by the magnetizing effects of the current flowing in the line.

In Fig. 1 but two stations are shown, one at each end of the line. Obviously intermediate or way stations could be added by merely placing the necessary keys and sounders in the line circuit at the desired points.

A more common practice is to employ a line relay at each station as the device directly responsive to the line currents, using this line relay to control a local circuit containing a local battery and a sounder. The reason for the choice of this slightly more complicated system for commercial practice is that the sounder, in order to make the necessary amount of noise, is required to be of a rather sturdy nature and is not as readily responsive to the comparatively small line currents as is the relay, which, having no other function than to be responsive,

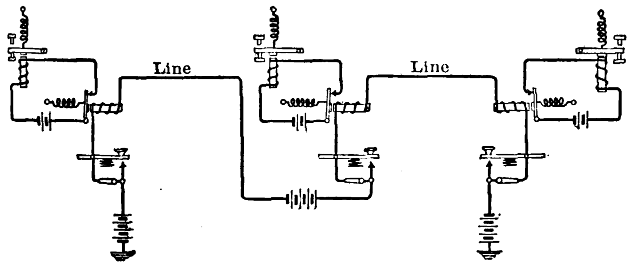

Fig. 2. Closed Circuit System with Way Stations

is readily made of the required sensitiveness. A line equipped for three such stations is shown in Fig. 2. While the constant flow of current in the closed-circuit system results in the use of a greater amount of current than would otherwise be necessary, it has the advantage of keeping the line under test at all times and of not requiring a line battery at each of the stations, as is the case with the open-circuit system.

Open-circuit System (Fig. 3). — This is largely used abroad. A battery is required at each station. Each key has a front and back contact so arranged

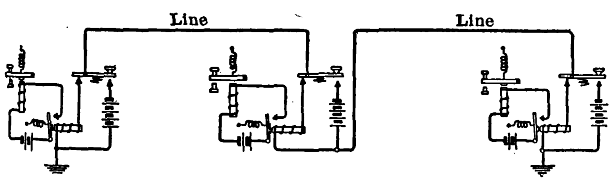

Fig. 3. Open Circuit System with Way Stations

as to hold the relay in the line circuit when the key is raised, and to cut the relay out of the line circuit and substitute the battery for it when the key is depressed. While, therefore, the line circuit is normally closed from one end to the other, the relays are not energized, since there is no current in the line. As a result, both the line and the local batteries stand in normally open circuits, and there is no waste of current. Besides requiring a line battery, sufficient for the operation of the entire line, at each station, this system does not hold the line and its instruments under automatic test conditions, which is automatically done by the constant flow of current in the closed-circuit system. A three-station open-circuit system is shown in Fig. 3.

Sound Reading.—In the first use of Morse telegraphy the received characters were recorded on a moving tape and subsequently translated. It was found in practice, however, that the operators soon learned to read what was coming over the wire by the clicking of the instruments, and, although this method of sound reading was condemned at first as being dangerous, it has survived to such an extent that the major portion of the telegraph work of the world is to-day received in this way.

Speed of Handling Messages by Morse System.—The speed of handling messages by Morse was limited by the speed of the receiving operator in writing down the message, as long as this was done in ordinary handwriting. The use of the typewriter for transcribing has, however, considerably increased the possible speed, and the limitation where the typewriter is used is that of the sending operator to "write" the Morse code. These speed limitations exist where the line conditions permit. A poorly working line may serve to reduce the possible speed far below the limitations prescribed by the ability of the operators. While speeds of over fifty words a minute have been attained by experts during short periods of time, and while operators often do send and receive thirty-five and forty words a minute in actual commercial work, the average under working conditions is far below this, and is probably under twenty words a minute.

DUPLEX SYSTEMS.—Duplex telegraphy involves the simultaneous sending of two messages in opposite directions over a single line. Two different methods are employed for making the receiving apparatus unresponsive to the home key. These two methods are termed the "differential" and "bridge" methods, respectively. There are also two different methods of sending impulses over the line, one of which depends on variations in current strength and the other on changes in current direction.

Differential Method (Fig. 4).—The differential method is readily understood from a consideration of Fig. 4, which shows a line relay having two windings in opposite directions. Current from the battery is supplied through one of these windings to the line, and through the other of these windings to the artificial line represented by a resistance at the left. The resistance and other characteristics of the artificial line are made approximately equal to those of the real line, so that impulses of current sent by means of the key from the battery to the line will produce no effect on the relay, because an equal current passes also through the artificial line. Obviously, however, there is no such differential action for incoming currents, and, therefore, the relay is responsive to currents from the distant station.

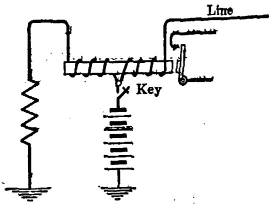

Fig. 4. Principle of Differential Method

The differential method is ordinarily employed in land telegraphy.

Bridge Method (Fig. 5).—The bridge method of rendering the home relay unresponsive to the home key and responsive to the distant key is illustrated in principle in Fig. 5. In this the resistances shown are so proportioned with respect to the resistance of the line that the line relay will receive no current upon closure of the key, for the

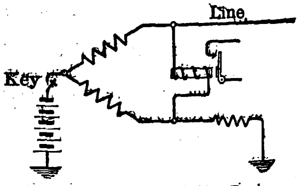

Fig. 5. Principle of Bridge Duplex

same reason that the galvanometer in a Wheatstone bridge does not respond when the bridge is balanced.

The bridge method finds its chief use in overland and in submarine telegraphy.

Stearns Duplex for Land Lines (Fig. 6). — The Stearns duplex for land lines operates on the increase and decrease in current strength, without changing the direction of current flow; and for the reason that it employs the differential method of making the home relay unresponsive to the home key, it is commonly referred to as the Stearns differential duplex system.

A simplified diagram of the Stearns differential duplex is shown in Fig. 6. It is to be noted that the batteries at opposite ends of the line have their opposite poles grounded, so that whether one or the other, or both, of the batteries are

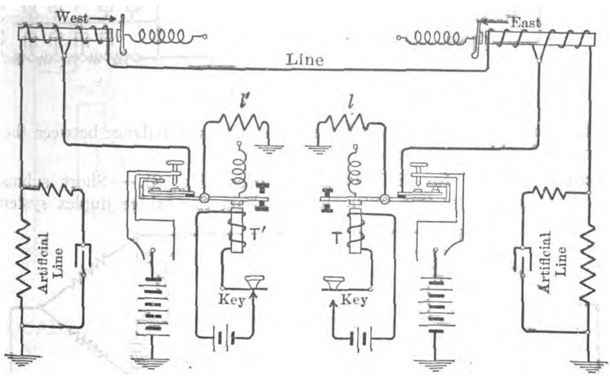

Fig. 6. Stearns Differential Duplex

in the circuit the current flows in the same direction. The key controls a local circuit of an electromagnetic transmitter T or T'. The tongue of each transmitter normally engages the contact on the under side of the bend in the lever; when the latter is attracted by its magnet upon the closure of the key, the tongue makes contact with the adjustable screw on the standard, and this prevents the tongue from moving farther upward, so that the making of this contact is immediately followed by the breaking of the normally closed contact of the tongue. Because these transmitters make one contact before breaking the other, they are called "continuity-preserving transmitters." When the key is open, the corresponding transmitter keeps its end of the line connected to ground through the resistance l, but upon the closure of the key the transmitter causes the substitution of the battery at that end of the line for this resistance. This resistance l sometimes is called the "spark coil," since its use tends to prevent sparking at the transmitter contacts, and its function is to compensate for the internal resistance of the line battery.

The artificial line shown at each station is composed of resistances and condensers arranged for ready adjustment, so as to balance not only for the resistance of the line, but for its capacity also.

Stearns Duplex for Submarine Cables. — Fig. 7 shows the Stearns duplex arrangement of terminal apparatus for cable working. This is a bridge method. The normal position of the keys grounds the cable conductor, thus discharging it. Alternately depressing the two keys gives the cable alternate negative and positive charges, thus sending dots and dashes. By moving the

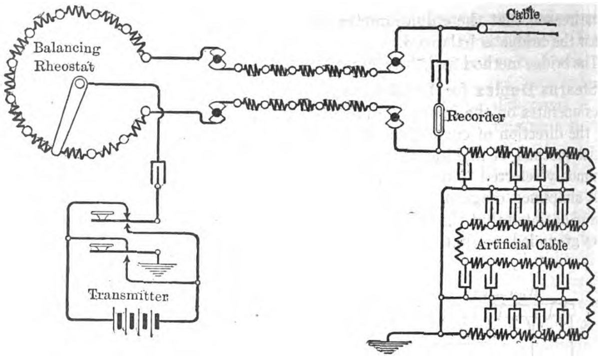

Fig. 7. Stearns Cable Duplex

arm of the balancing rheostat, delicate adjustments of balance between the real and artificial cables are secured.

Jacobs' Duplex for Submarine Cables (Fig. 8). — Short submarine cables frequently have two conductors, making the bridge duplex system of

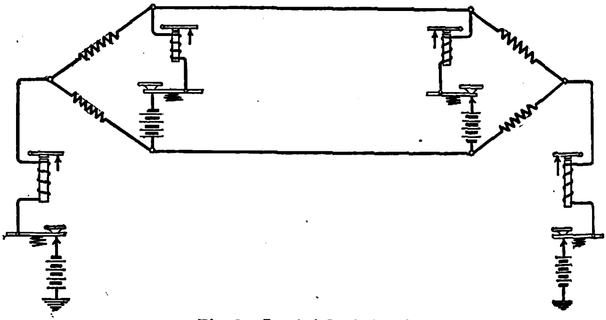

Fig. 8. Jacobs' Cable Duplex

Fig. 8 available. This is similar to simplex working in combined telephony and telegraphy. This method is found preferable to using each conductor separately for the two transmissions, since it avoids inductive interference between the two wires.

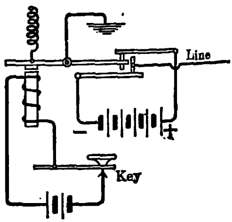

Fig. 9. Pole-changing Transmitter—Polar Duplex

Polar Duplex (Fig. 9 and 10). — The polar duplex depends for the principal feature of its operation on the fact that a polarized relay will move its armature oppositely for opposite directions of current. The key used in sending operates to close and open a local circuit which controls a pole-changing transmitter. The action of this is made clear in Fig. 9. With the key closed, as shown in that figure, the negative side of battery will be connected to line and the positive side to ground.

With the key open, the reverse will be true. The circuit of the polar duplex is shown in Fig. 10.

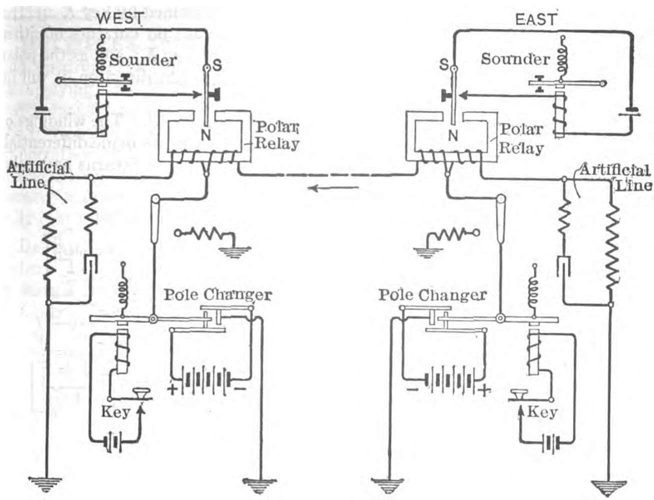

Fig. 10. Polar Duplex

QUADRUPLEX SYSTEMS. — In quadruplex systems four messages, two in each direction, may be transmitted simultaneously over a single line wire.

Edison Quadruplex (Fig. 11 and 12). — The Edison quadruplex depends for its principle of operation on a combination of the two duplex systems, the Stearns and the polar just described. At each station two relays are provided, one, the neutral relay, responsive to currents in either direction, and the other, the polar relay, responsive only to currents in one direction. At each

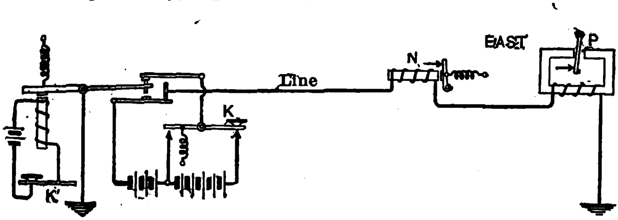

Fig. 11. Principle of Edison Quadruplex

station also two key-controlled transmitters are provided, one of which operates, as in the polar duplex, to change the direction of current in the line and the other, as in the Stearns duplex, to increase and diminish the strength of current flow.

The principle of transmitting in one direction by means of the Edison quadruplex is indicated in Fig. 11, where N is the neutral relay and P the polar relay at the East station. K and K' are transmitting keys at the West station, key

K operating to alternately weaken and strengthen the line current, and *K'* operating as a pole changer to reverse the line current. As shown, the line will always have some current flow, the amount being determined by key *K* and the direction by key *K'*. As the neutral relay will operate on currents of either direction, if strong enough, it will be responsive only to key *K*; and as the polar relay will operate on either current strength, if in the right direction, it will be responsive only to key *K'*.

The circuits of the Edison quadruplex are shown in Fig. 12. The windings of the neutral relays *N* and of the polar relays *P* are in each case made differential, for the same reasons as pointed out in connection with the Stearns and polar

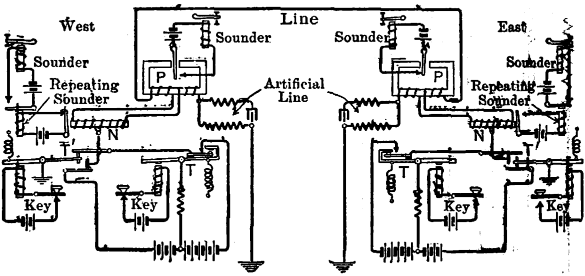

Fig. 12. Edison Quadruplex

duplex systems. At each station of the "quad" system one winding of each relay is in the line, and the other in the artificial line. As will be seen from Fig. 12, the two transmitters at each station modify the main battery current, as pointed out in connection with Fig. 11, the continuity-preserving transmitter *T* controlling the current strength and the pole-changing transmitter *T'* controlling its direction.

Key Systems for Quadruplex Working. — In the quadruplex so far described, the current was supplied by batteries, and the strength-varying transmitter operated to accomplish its purpose by alternately cutting a portion of the line battery out of and into the circuit. Where dynamos furnish the current, a different scheme is employed. One system, known as the Field key system, is illustrated in principle in Fig. 13. Two dynamos are employed, having opposite poles grounded. The pole changer merely chooses between the two live poles for securing its reversals in polarity. The continuity-preserving transmitter varies the current strength in the line by changing the resistance relations as shown. Thus, when the key is closed, the 1200-ohm resistance is short-circuited and the 900-ohm "leak" resistance to ground is cut off. The

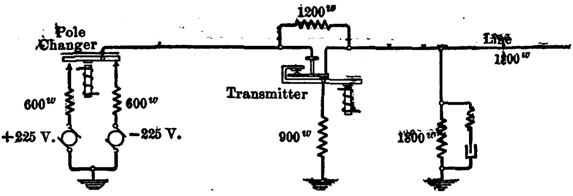

Fig. 13. Field Key System

current under these circumstances flows to line at full strength. When the key is opened, the 1200-ohm resistance is introduced in the line and the 900-ohm leak is made effective. The resistances shown are those for an 1800-ohm line.

MULTIPLEX SYSTEMS. — The term "multiplex" should include duplex and quadruplex systems, but practice has been otherwise, and has resulted in applying the term "multiplex" principally to a system wherein two synchronously moving switches, one at each end of the line, serve to connect the corresponding sets of telegraph instruments momentarily and successively in operative relation with the line. While each set of instruments, therefore, is connected with the line for only a small fraction of the total time, the successive connections recur so rapidly as to afford, to all intents and purposes, a practically continuous use of the line.

Delany Synchronous Multiplex System (Fig. 14). — The principle of the Delany synchronous multiplex system is shown in diagram in Fig. 14. Six sets of instruments, each consisting of a pole-changing key and a polar relay, are shown at each end of the line. The two switch arms of the synchronous rotary

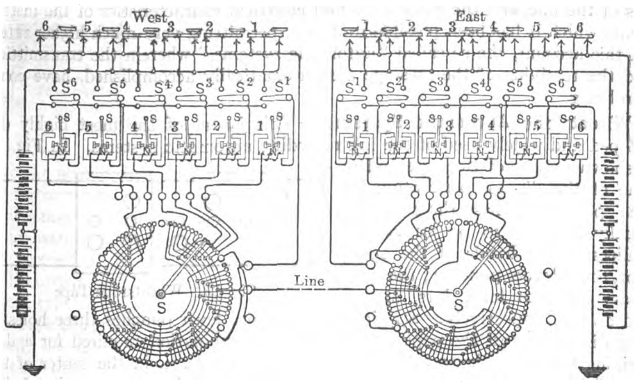

Fig. 14. Delany Synchronous Multiplex

switches S are made to revolve in unison, so that the correspondingly numbered sets of instruments at each end will be simultaneously connected with the line. As the switch arms make about 180 revolutions per minute, and as each set of instruments is connected with the line twelve times at each revolution, it follows that each set of instruments is connected with the line thirty-six times per second. This is a much shorter interval than that required to make the shortest dot, and, therefore, any closure of a key which an operator may make will necessarily cover a time during which at least one connection will be made with the line. In the particular embodiment of the Delany system shown polarized relays and pole-changing keys are used, the advantage of this being that the relay armature will remain in the position to which it was last brought by a current impulse, in spite of the rapid interruptions caused by the synchronous switch. A small switch lever, S^1, S^2, etc., is associated with each key and relay and is moved by the operator to one or the other of its positions, according to whether he is sending or receiving.

The synchronizing mechanism for the switch movements is ingenious and interesting. The two arms are each driven by step-by-step motors, the driving impulses being regulated by means of tuning forks, as accurately tuned to each

other as possible. Obviously, complete synchronism could not be obtained by this means alone, and, therefore, the two driving devices are each brought into association with the line by the rotary switch arms six times during each revolution, the arrangement being such that if one switch arm arrives on one of the dead or synchronizing contacts slightly in advance of the other, it will apply a corrective measure to its motor device, which will tend to slow it down. This corrective measure is in the form of an electromagnet, in the field of which the tuning fork vibrates, and the energization of this magnet exerts a retarding influence on the rate of vibration, and, therefore, on the rate of rotation of the synchronous switch.

This system has been used to some extent commercially with as high as six simultaneous transmissions on comparatively short lines, and four or fewer on long lines. Obviously, the time constant of the line enters as a limiting factor to a greater extent than in the ordinary systems of Morse telegraphy.

AUTOMATIC SYSTEMS. — The limitations in speed of transmission over an ordinary manually operated telegraph line are mainly those due to the ability of the operators to transmit and receive, the electrical characteristics of the line, and the mechanical and electrical characteristics of the instruments which it has been possible to devise, permitting very much higher rates. On this account, the so-called "automatic systems," wherein the transmitting and the receiving of the message are automatically accomplished, have come into being.

Wheatstone Automatic System. — This is one of the most highly developed and widely used of the ink recording automatic systems. In Fig. 15 is shown a piece of the tape and a plan of the die for perforating it. The perforator has three levers usually adapted to be struck by mallets in the hands of the operator, these levers punching the necessary holes to form dots, spaces and dashes, respectively. Striking the left-hand lever punches three holes, 1, 2, 3, directly across the paper, this being the combination required for a dot. Striking the center lever punches a single small hole, 4, in the center of the tape, thus making a space, while the third or right-hand lever punches four holes, arranged as 5, 6, 7 and 8, thus setting up a combination for a dash. The function of the small holes along the center line of the tape is to effect the proper driving of the tape, these being engaged by the points of a star wheel in connection with the feeding mechanism. As this tape is driven through the transmitter, one row of larger holes determines the intervals at which the positive pole of the battery shall be put to line, and the other row of large holes the intervals during which the negative pole is connected. As the two members which engage these holes are arranged so that one is slightly in advance of the other, it follows that the holes 1 and 3 will cause first a negative impulse, immediately followed by a positive impulse, this being the combination for a dot. The two holes, 5 and 8, will likewise cause a negative, followed by a positive, impulse, but the two will be separated by an interval of time, this being the combination for a dash. The Wheatstone is thus a so-called "double-current" system, depending for its operation on the actual reversal of the line current.

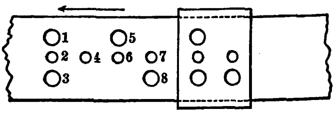

Fig. 15. Wheatstone Tape

Wheatstone Receiver. — The receiver of the Wheatstone system is in the form of a polarized relay, the armature of which will stay in either of its extreme positions even though the current which moved it there ceases. The inking is done by a very small ink wheel which is constantly rotated in close proximity to the moving paper tape. The shaft on which this ink wheel revolves

is so mounted as to be deflected by the movements of the relay armature. The ink wheel receives its ink on the back stroke from another wheel which revolves in a tank of ink. On the forward stroke the ink wheel is brought close enough to the moving paper tape to make a mark, although there is no actual contact between the wheel and the tape.

Chemical Systems. — These systems, once employed in commercial work to a considerable extent, have been in large measure superseded either by the ink recording systems or by ordinary Morse. They present possibilities for future development, however, which give them more than an historic interest.

Anderson Chemical Automatic System (Fig. 16). — The salient points of the Anderson chemical automatic system are shown in Fig. 16. The

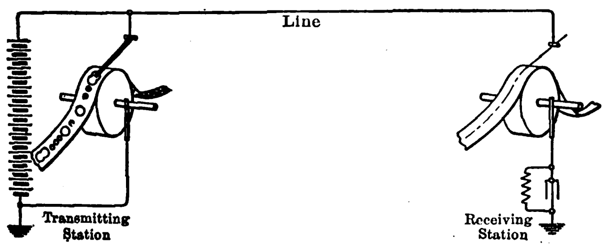

Fig. 16. Principle of Chemical Automatic System

passage of a hole in the transmitting tape under the contact pen serves to short-circuit the transmitting battery and thus cause a cessation of current in the line. The condenser at the receiving end, previously charged by the flow of current from the battery, then discharges into the line, this being intended to cause an actual reversal of current flow. This is an interesting example of so-called "double-current" working with a single battery. At the receiver the chemically saturated tape passes under a contact pen, so that the current is compelled to flow through the paper. Its flow decomposes the solution and marks the paper, as already described. The reverse flow of current from the condenser tends to prevent the occurrence of "tailings."

Speed of Anderson System. — This system, like the Wheatstone, records in dots and dashes, and, according to Maver, it has been found capable of transmitting 600 words per minute over a 1000-mile line having a resistance of 2500 ohms, under all sorts of weather conditions. On a shorter line, 360 miles in length, having a resistance of about 700 ohms, the astonishing rate of 3000 words per minute has been accomplished.

WRITING TELEGRAPHS OR AUTOGRAPHIC SYSTEMS. — Writing or autographic telegraphs are to be distinguished from printing telegraphs in that they write the received messages in script, while the printing systems actually print them as from type.

In these systems the message to be transmitted is written down by the sender as with a pen or stylus, while at the receiving end a recording pen simultaneously executes the same movements and thus writes the message in the same or very similar handwriting. Nearly all autographic systems depend on resolving the movements of the transmitting pen or stylus into two component straight-line movements at right angles to each other, electromagnetically reproducing these component rectilinear motions at the receiving station, and recombining them there into the resultant movement, which, therefore, traces a path closely approximating that originally made by the sending stylus.

Robertson System.—Fig. 17 is a schematic diagram of this system and clearly illustrates the principle of autographic systems. Two line wires are employed, each including a battery and a variable-resistance element

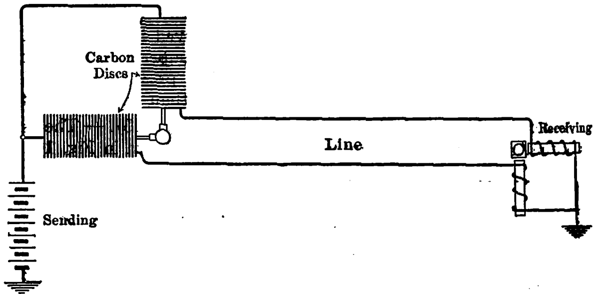

Fig. 17. Principle of Robertson System

at the transmitting station, and an electromagnet at the receiving station. The variable-resistance elements are composed in this case of piles of carbon discs arranged at right angles to each other, these being so related to the transmitting stylus that its movements in writing will cause, due to variations in pressure on the carbon discs, corresponding variations in resistance in the paths through the discs. The receiving pen is actuated by the armature common to the two magnets at the receiving end. As the respective pulls of these two magnets are at right angles and vary as the strength of the currents flowing, the two components of the transmitting stylus are reproduced and these are recombined to produce the corresponding movements of the receiving pen.

Telautograph.—This is another autographic system, due largely to Elisha Gray. It employs two wires, and like the system just described resolves the complex motion of the transmitting pencil into two rectilinear components at right angles, reproduces these at the distant end, and recombines them to obtain the facsimile writing. The transmitting stylus operates two bell-crank arms carrying rollers which operate over rheostat contacts to cause the variations in resistance and current strength. At the receiving end the pen is attached to the arms of two bell cranks which are operated on by solenoids, which lie in uniform magnetic fields and which, under the influence of the varying currents passing through them, cause the required movements of the bell cranks.

Pollak-Virag System.—In this the message is prepared by perforating a tape, the passage of which through the transmitter results in currents being sent over the two line wires in proper sequence, direction and strength to cause the receiving instrument to record the message in a style very similar to longhand writing. Two circuits are obtained from the two wires; one the metallic circuit and the other the two wires in parallel with earth return. At the receiving end two instruments closely resembling telephone receivers are affected by the currents received over the two circuits. The diaphragms of these receivers control the movements, on horizontal and vertical axes, respectively, of a small mirror. A ray of light reflected from this mirror is caused to move upon a rapidly moving strip of light-sensitized paper, and the co-ordinated movements on the two axes of the mirror under the influence of the currents received result in writing. The photographic paper is automatically passed

through the necessary developing and fixing baths, the time required in this process being only about twelve seconds.

PRINTING TELEGRAPHS. — These are systems in which the received messages are automatically recorded in print. Most printing telegraph systems depend upon synchronism being maintained between the two wheels at the transmitting and receiving stations; although in some systems, such as the Murray, for instance, no such requirement exists.

Ticker Systems. — In the ticker systems, which are widely employed for transmitting stock-market quotations, the type wheels are moved synchronously a step at a time, either by causing the same set of line impulses to affect each, or by causing the wheel at the sending station, in its revolution, to transmit impulses which turn the distant wheel. The wheels must not only revolve at the same rate, but a given letter on each must come opposite a given fixed point simultaneously. By stopping the wheels when the desired letter is brought opposite the paper, an impulse of different character is sent which causes the imprint to be made. Some ticker systems operate over one line wire, and the impulses which cause the rotation of the type wheel occur so rapidly as not to affect the printing magnet, but upon their cessation the printing magnet included in the same circuit is brought into play. Many of the ticker systems operate over two line wires and employ two type wheels, one carrying letters and the other figures. Means are provided for shifting either the wheels or the tape, so as to print from either as desired.

The Hughes System. — This is largely employed in Europe, and is a synchronous type-wheel system in which the type wheels revolve continuously rather than by step-by-step movements. Electric motors furnish the driving power. The wheels are adjusted to revolve at as nearly the same rates as possible and suitable corrective means are brought into play over the line wire to maintain complete synchronism. The transmitting apparatus resembles the keyboard of a piano, a key being assigned to each character. In connection with this keyboard there is a rotating contact device revolving in synchronism with the type wheels, and the arrangement is such that the depression of any key will cause a contact to be made at the exact instant when the letter corresponding to that key is in printing position at both instruments.

Speed of Hughes System. — The Hughes system is capable of operating with great accuracy at a speed in the neighborhood of from thirty to forty words per minute.

Phelps System. — The Phelps system is a modification of the Hughes and operates on the same general principles. It has superseded the Hughes system in the United States.

The Buckingham System. — One difficulty with the ordinary step-by-step system is that the great number of impulses required per letter necessarily slows down the speed. The Buckingham printing system is designed to operate with a maximum of six current impulses per letter, the necessary choice between letters being effected by various combinations of short and long current impulses in either direction, with short and long intervening spaces. The Buckingham system resembles the Wheatstone, in that the spaces are made by negative currents and the dots and dashes by positive. As in the Wheatstone system, also, the message is prepared by perforating the tape in such manner as automatically to send the required combinations of dots, dashes and spaces, but a different code is used, in which each letter and other character is composed of three positive impulses, dashes or dots, or both, variously combined with long or short negative impulses, corresponding to spaces. By a most ingenious mechanism at the receiving end these positive and negative currents, instead

of being received in dots and dashes on a moving tape, are made to effect proper selection of the various printed characters, and to print them in desired order in page form. The type wheels are four in number, all mounted side by side on the same shaft and rotating together. Each type wheel carries eight letters or characters, making thirty-two in all. By means of levers, operated by electromagnets, the type wheels are, under the action of the code impulses, given any desired lateral or rotary motion to bring the required type face into printing position. The space between the letters is utilized to give the printing impulse.

Tape-punching Machine for Buckingham System.—The tape-punching machine of the Buckingham system employs a standard typewriter keyboard, one depression of the key effecting the tape punching for a complete character. The maximum speed possible is about 80 words per minute, as against 20 to 40 words per minute in the mallet method of punching Wheatstone tape.

Speed of Buckingham System.—This system has a possible average speed of transmission of about 100 words per minute, and is reported to have worked on a duplex circuit between New York and Chicago with an average speed of 80 words per minute in each direction.

The Barclay System.—This has been employed extensively by the Western Union Telegraph Company, and resembles in many respects the Buckingham system. It uses the same code alphabet and the same general method of transmitting, but the impulses received result in the operation of a group of magnets which in turn affect the operating levers of a Blickenderfer typewriter, which does the actual printing. The printing is done on ordinary message blanks.

Speed of Barclay System.—The rate of transmission possible is approximately 100 words per minute in each direction when operated as a duplex.

The Rowland System.—This is one of the most highly developed of the printing systems, and was for a time used to considerable extent by the Postal Telegraph Cable Company between New York and Chicago, and on other circuits. Essentially the system is a one-way quadruplex, but as it is capable of being worked duplex it becomes in effect an "octoplex," transmitting four simultaneous messages in each direction over one line wire.

The line current employed is alternating, generated by a dynamo at one end, which runs a synchronous motor at the other, thus effecting the required synchronism. The necessary current combinations to effect the selection and printing of a given letter are brought about by reversing certain of the half waves in each group of line current waves. The simultaneous transmission of four messages in one direction is provided for by an adaptation of the multiplex system, a distributing switch giving each set of four transmitting and receiving instruments successive and simultaneous control of the line. Since each letter is represented by a specific combination of positive and negative currents, it is possible by means of these combinations to effect the closing of the proper local circuits at the receiving end to cause the paper to be pressed against the type wheel at the time when the letter required is opposite it.

Speed of Rowland System.—Each transmitter and receiver has a speed of about 30 words per minute, making a total transmission of 240 words per minute when the octoplex method of working is employed.

The Murray Automatic System.—This is a non-synchronous printing system. Messages are first prepared by perforating a paper tape. This tape is then fed into the transmitting device and permits currents to flow over the

line in such a manner as to cause the receiving device, which in itself is a tape-perforating machine, to perforate another tape there. This receiving tape is a replica of the transmitting tape, and when passed through an automatic typewriter the perforations are translated into Roman type letters, the message being in page form.

Speed of Murray System. — This system is capable of transmission speeds upward of 200 words per minute, but speeds of from 100 to 125 words per minute have been found to be the best for practical working.

TELEPHONE INSTRUMENTS AND CIRCUITS. — (*See also Standardization Rules of the A.I.E.E.; Telephone Lines; Telephone Traffic; Wireless Telephony.*)

The chief subjects treated in this article are:

The telephone transmits speech and other sounds by this cycle of action: sound waves in air vibrate a diaphragm; this vibration produces fluctuating current in a line joining the transmitter to a distant receiver; the fluctuating current produces vibration in the diaphragm of the receiver; these vibrations produce sound waves in air.

Bell's original telephone utilized one device as both transmitter and receiver. It survives in its original form as a receiver, but seldom is used as a transmitter, more powerful devices having supplanted it.

RECEIVERS. — The original telephone consisted of a magnet, a coil of fine wire and a diaphragm, arranged as in Fig. 1. *d* is a diaphragm, *m* is a magnet,

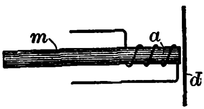

Fig. 1. Principle of Permanent Magnet Receiver

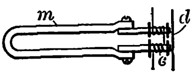

Fig. 2. Principle of Bipolar Receiver

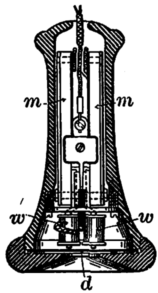

Fig. 3. Section of Bipolar Receiver

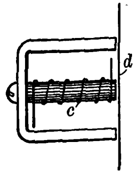

Fig. 4. Principle of Direct Current Receiver

and *a* is a coil. The magnet was first made of soft iron, getting its magnetism from direct currents in the line; a permanently magnetized bar of hard steel with soft iron poles (Figs. 2 and 3) soon was substituted for this soft iron core.

Bipolar Receiver. — The bipolar receiver is the present standard form, as in Fig. 2, in which *d*, *m* and *c* represent, as before, the diaphragm, magnet and coil. Both poles of the permanent magnet are presented to the diaphragm, being extended by soft iron pole pieces, each carrying a bobbin wound with fine, silk-covered or enameled wire. The wires of the two bobbins are connected in series. When used to transmit speech, such an arrangement is called a magneto transmitter.

The magnet, winding and diaphragm of a receiver are assembled in a case of hard rubber or an imitation thereof, adapted at one end to fit the ear and at the other to hang on a hook switch. Fig. 3 is a section of a typical assembled receiver. *m, m* are permanent magnets, arranged to produce opposite poles at the ends of the soft iron cores carrying the windings *w, w*; *d* is the diaphragm. In good types of receivers the entire mechanical arrangement of parts is supported from the ear end of the shell and not from the other end. This precaution is necessary in order to prevent the adjustment of the pole pieces to the diaphragm being upset by the difference in expansion of the shell and magnet.

"**Direct-current Receiver** (Fig. 4).—For use in lines carrying direct current during conversation, as in common-battery systems, the iron-core type of receiver recently has been revived. They are extremely simple and cost little to make. It is not yet established that they are as efficient as permanent-magnet receivers, but the difference seems to be slight.

The Monarch Telephone Manufacturing Company uses a receiver which has two pairs of windings, as in Fig. 5. One pair is of large impedance, serving to magnetize the cores, while the other, of smaller impedance, serves to actuate the diaphragm. Direct currents pass through both pairs of windings, their magnetizing effects being additive, but the direct current through the coils farther from the diaphragm is the larger. Voice currents pass through both pairs of windings and their effects are additive, but the voice currents through the windings nearer to the diaphragm are the larger.

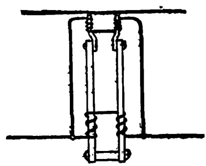

Fig. 5. Monarch Receiver

Head Receiver.—A head receiver is a compact one carried by a band fitting the operator's head, leaving her hands free. The compactness is gained by making the magnets small and placing them parallel with the diaphragm.

TRANSMITTERS (Figs. 6 and 7).—Present standard carbon transmitters are many times more powerful than the best magneto transmitters. Carbon transmitters and their circuits take many forms, but in all the function is to produce current fluctuation as a consequence of diaphragm vibration caused by sound.

The elements of a transmitter are a diaphragm, two polished solid carbon electrodes, and a charge of polished carbon granules. Vibration of the diaphragm moves one electrode to compress and release the granules between the electrodes. Fig. 6 illustrates the elements; *d* is the diaphragm, *m* the movable and *f* the fixed electrode. Fig. 7 is a section of a typical granular carbon transmitter.

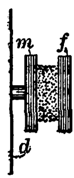

Fig. 6. Principle of Transmitter

All carbon transmitters operate by varying the resistance of some material proportionally to movement of the diaphragm. Receivers, on the other hand, are caused to operate by a varying magnetic flux. The reason for the excellent action of carbon in varying its contact resistance under pressure is not known.

RINGERS OR BELLS (Fig. 8).—The present standard telephone signal is a two-gong bell, actuated by alternating current. Its principle is that of the polarized telegraph relay. Its construction, as in Fig. 8, is of two coils, a permanent magnet *N*, two gongs and an armature *S*.

Magneto Generator (Fig. 9).—The bells of telephones in all exchanges are rung by alternating current sent out from the central office power plant. In magneto systems the subscriber calls the central office by operating a magneto generator, which is a part of his telephone, and with this generator

the subscriber also rings other bells on the same line. The magneto generator is a standard part of subscribers' equipment for rural and other party lines, being the best way for a subscriber to do signaling between various telephones on one line. The armature has many turns of fine wire (Nos. 32 to 36 B. & S.

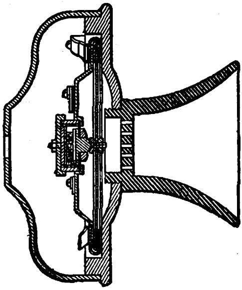

Fig. 7. Granular Carbon Transmitter

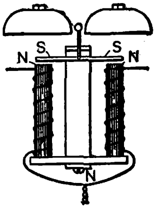

Fig. 8. Alternating Current Ringer

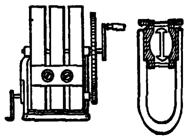

Fig. 9. Magneto Generator

gage), of a resistance of from 300 to 1000 ohms. A frequency of 20 cycles and an e.m.f. of from 60 to 80 volts can be produced by turning the crank briskly by hand.

BATTERIES. — (*See articles on Batteries.*) The transmitter of a telephone set requires direct current and produces from it the alternating (or otherwise fluctuating) voice currents, which pass over the line to the distant receiver. A central storage battery furnishes the direct current over the line in "common battery systems," or "central energy systems." A primary battery furnishes the direct current in systems not having a central storage battery for the purpose.

Dry Cells. — The primary battery usually is of the dry cell type and is associated directly with the telephone set. Such an arrangement is called a local battery set. The cells have an e.m.f. of about 1.5 volts, and can give a current on short circuit as high as 15 amperes. Dry cells, designed particularly for local battery telephone service, have higher internal resistance than those intended for gas engine ignition and other heavy current intermittent work. Longer life, with only slightly less efficiency, is obtained by increasing the internal resistance. Dry cells may be used for but a few minutes at a time.

Gravity Cells. — Other types of primary cells are used to energize transmitters. Gravity cells are suitable for operators' telephones in small exchanges, and can furnish current steadily with no periods of rest. Gravity cells must not stand long on open circuit. They give about 1 volt per cell. Three or four in series are suitable for a transmitter.

Fuller Cells are suitable for heavy service (many long conversations per day), and also can stand on open circuit without harm. They approach nearest the storage battery in e.m.f. (about 2 volts) and output. They are sloppy and costly to maintain and are used less widely now than heretofore.

Storage Batteries give good results in local battery sets; they require charging by direct current from outside themselves, however, and suffer from the lack of frequent charges. They are suitable for but few conditions of local battery use for those reasons. The most widely used method of charging storage batteries is by motor-generator sets, the motor being adapted to the source of energy and the generator being shunt wound.

POLE CHANGERS. — Ringing current in central offices is usually produced by alternating current generators or by pole changers. The latter are vibrating contact-makers having a natural frequency corresponding to the frequency of the current desired. They are operated by direct current from a storage battery or other source. The Warner pole changer, Fig. 10, is widely used for ringing ordinary telephone bells at a frequency of from 16 to 20 cycles per second. Pole changers of multiple frequency are also used to ring harmonic bells on party lines.

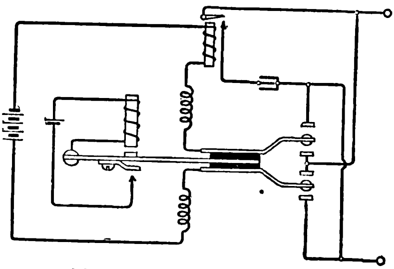

Fig. 10. Warner Pole Changer

IMPEDANCE COIL. — An impedance coil is a single coil of wire wound on an iron core.

INDUCTION COIL. — A step-up transformer used in a telephone circuit is called an induction coil in telephone parlance. Fig. 11 shows the use of such a transformer in a local battery set. The battery and the carbon button are connected in series with its primary winding; the line and the receiver are connected in series with its secondary winding. The function of the induction coil is to convert the local variations of direct current of low e.m.f. into alternating currents of higher e.m.f. in order that it may pass over the line with less loss.

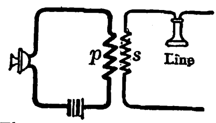

Fig. 11. Induction Coil in Local Battery Set

Local battery induction coils have a large ratio between the two windings. The primary winding is of low resistance and of fewer turns than the secondary winding. Single silk insulated wire is used for both windings; practice varies as to wire sizes and turns; a representative example has 350 turns of No. 20 B. & S. gage wire in the primary and 2400 turns of No. 30 B. & S. gage wire in the secondary. Other examples use from 200 to 700 turns in the primary, 700 to 5500 turns in the secondary, No. 20 to No. 28 B. & S. gage wire in the primary and No. 26 to No. 36 B. & S. gage wire in the secondary.

The induction coils in common battery sets have different functions from those in local battery sets. Figs. 12 and 13 show two forms of common battery telephones using them. In most cases one function of the induction coil is to in-

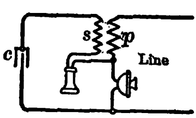

Fig. 12.

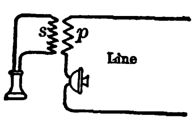

Fig. 13.

sulate the receiver from the direct current of the line, so that its permanent magnetism never shall be opposed by direct current flowing in its coil. In Fig. 12 the induction coil has the further function that, co-operating with the condenser *c* it assists the transmitter to convert the direct current of the line into an alternating voice current. The condenser alternately receives and gives up charges, responsive to the state of the varying resistance of the transmitter.

This particular transforming function is lacking in all circuits having the general type of Fig. 13.

REPEATING COIL. — A repeating coil is any transformer used in a telephone circuit. A one-to-one ratio repeating coil is frequently connected in such a manner that when equal currents flow through each winding in the same (or opposite, depending upon the point of reference) direction, the magnetic fields of the two currents *neutralize* each other, and, therefore, practically no impedance is offered to the flow of such currents, but each winding by itself has a high impedance. As the result of such an arrangement the repeating coil offers a high impedance to any current tending to flow through one winding which is not accompanied by an equal current in the proper direction in the other winding. One application of a repeating coil is shown in Fig. 29. One of the windings of a transformer or induction coil can also be used as a repeating coil as illustrated in Fig. 32.

HOOK SWITCH. — The time during which a subscriber's telephone is idle much exceeds the time in which it is in use. *When idle, it must be ready to receive or to make a call.* When in use, its transmitter must be able to receive direct currents and its receiver to receive voice currents. The hook switch makes these changes *automatically.*

TELEPHONE REPEATERS. —A telephone repeater is similar in principle to a telegraph relay. A repeater to be successful must be designed so that a weak current passing through the "primary circuit" of the repeater will cause a local source of energy located at the repeater to set up a current wave in the "secondary" of the repeater of practically the same form as in the primary, but of increased amplitude; in addition the secondary wave thus set up must not distort the primary wave. To be commercially successful a repeater must be so designed that it can be shunted or bridged across the line and be used for transmitting in both directions. The simplest form of repeater is a receiver which has its diaphragm connected mechanically to the movable electrode of a transmitter. Repeaters are used to a limited extent, but unless special care is used in locating the instrument at the "electrical center" of the line and in keeping it carefully adjusted, the secondary wave set up is reflected back into the primary or transmitter circuit, is again amplified by the repeater, and so on, which cumulative action may be such as to produce a "howling" noise and render the repeater useless. Pupin, the inventor of the loading coil, has suggested the use of an induction motor driven above synchronism as a repeater, but up to the present such a device has not been perfected.

PROTECTIVE DEVICES. — Telephone apparatus and lines are protected from damage due to abnormal currents by means of fuses supplemented by two important co-operating elements. The latter are heat coils or "sneak current arresters," and air-gap arresters. Heat coils operate by short circuiting a pair of contacts when small currents flow for long times or when large currents flow for short times. Air-gap arresters operate when potentials of 350 volts or more exist at their terminals. The operation of either a heat coil or an air-gap arrester short circuits the line, grounds the wires in trouble, and blows the fuse. On account of the high resistance of the telephone instruments, an abnormal current in the line may not be large enough to blow a fuse unless there is a dead short circuit. The heat coil insures such a short circuit whenever the amount or duration of the current exceeds a safe value.

The relation of the three elements to each other and to lines and apparatus is shown in Fig. 14. The fuses should be located at the point of junction between wires which are "exposed" and wires which are "not exposed" to possible contact with a source of dangerous current. All aerial wires and aerial cables are

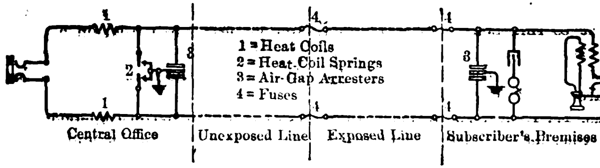

Fig. 14. Arrangement of Protective Devices

exposed. Underground and indoor wires are to be considered unexposed, if the indoor wires are run in accordance with good rules, such as those of the National Electrical Code.

TELEPHONE SETS. — The several elements necessary at a subscriber's station are associated to form series magneto sets, bridging magneto sets and common battery sets.

Series Magneto Sets (Fig. 15) are suitable for use on single party lines, and are widely so used in exchange practice, and, unfortunately, to some extent on lines having more than one telephone (party lines). Fig. 15 is the circuit of a series set. When the receiver is on the hook, the bell is connected between the terminals of the set, the battery and receiving circuits both are open, and if the generator is not turned its armature winding is shunted. When the generator is turned in calling, the shunt is broken automatically.

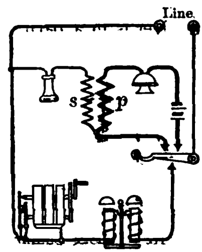

Fig. 15. Series Local Battery Magneto Set

In series sets the voice currents must pass in series *through* all but one of the ringers of a line. The impedances of the ringers, therefore, must be as *low* as possible, yet high enough to respond to ringing current of reasonable e.m.f. 80 to 100 ohms is the usual resistance for both coils of a series ringer. The cores usually are shorter than in bridging ringers.

Bridging Magneto Sets (Fig. 16) are better than series magneto sets for party lines. The ringer is bridged across the line permanently. The generator is bridged across the line when the crank is turned. The receiver and transmitter circuits are closed when the hook is up. Three of the four circuits of the set are open when it is not in use, as in Fig. 16.

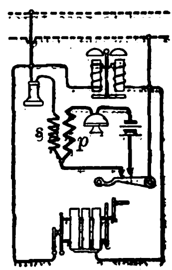

Fig. 16. Bridging Magneto Set

In bridging sets the voice currents must pass *by* all of the ringers of a line. The impedance of the ringers, therefore, must be as *high* as possible, yet low enough to respond to ringing current of reasonable e.m.f. 1000 to 1800 ohms is a usual resistance for the two coils of a bridging ringer. The cores are usually longer than in series ringers.

Common Battery Sets (Figs. 17–19) have no magneto or local battery and can, therefore, be used only on lines leading to a central office. A storage battery at the central office, common to all the lines, supplies current to them for two purposes, for talking and for signaling the operator; hence the name "common battery." The absences of the magneto generator and the local battery simplify construction

and operation of the instrument. Common battery telephones cannot send out current to ring bells, as can magneto telephones; when used on a party line they can, therefore, call each other only indirectly, by asking the central office operator to send the necessary ringing current over the line. Common battery sets are nearly always bridging sets.

Figs. 17, 18 and 19 are typical circuits of common battery telephones. Fig. 17 is that used by the Associated Bell Telephone Companies and in Western Electric Company's apparatus throughout the world. As the condenser is "opaque" to direct current, but "translucent" to alternating current in a degree dependent upon the frequency, no direct current from the central office normally will flow through the set when the hook switch is down, but alternating current from the central office can actuate the ringer. When the switch-hook is up, direct current from the central office flows through the transmitter *t* and the primary *p* of the induction coil.

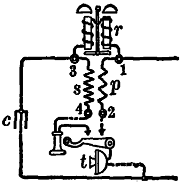

Fig. 17. Bell Common Battery Desk Set

In the circuit of Fig. 18, used by the Kellogg Switchboard & Supply Company, the ringer, in series with a condenser C_2, normally is bridged across the line. When the switch-hook is up, the transmitter is in series with the line and can vary its current. The receiver is in a path "opaque" to direct current, but "translucent" to voice current, because of the condenser C_1. The receiver path, including the condenser

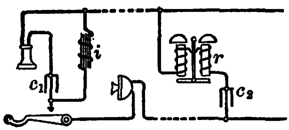

Fig. 18. Kellogg Common Battery Set

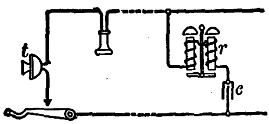

Fig. 19. Desk Set with Direct Current Receiver

C_1 is shunted by a coil *i* of low resistance but of high inductance, which is opaque to voice currents but translucent to direct currents. No direct currents can pass through the receiver.

The circuit of Fig. 19 is one in which all of the direct current intentionally is allowed to pass through the receiver. The latter has no permanent magnet (i.e., is of the "direct current" type, Fig. 4 or 5), and depends on the direct line current from the central office to magnetize its core.

Wall and Desk Sets. — Telephone instruments are assembled for use in two forms, wall sets and desk sets. The latter also are called portable sets, having the receiver, transmitter and hook switch combined into a unit which can be carried about. Wall sets are self-contained, having space for batteries if needed. In local battery and common battery desk sets the ringers are separately mounted, usually upon a wall. Local battery desk sets in addition require housing for batteries, and magneto desk sets require separately mounted hand generators.

A desk set is connected to line and ringer, and to battery and generator, if used, by a flexible cord. The number of strands in the cord depends on the type of circuit used, and on whether the induction or impedance coil, if used, is mounted in the portable set itself or on the wall with the ringer. In Figs. 17, 18 and 19 the parts of the circuit carried by cords between the portable and fixed portions of the set are shown by dotted lines.

Desk sets are more convenient for use but are more costly to maintain than are wall sets. They fall frequently, breaking transmitter mouthpieces, receiver shells, and other parts. Supporting arms for desk sets minimize this breakage.

Extension Set. — An extension set is a set used as an auxiliary to a regular set; the extension set usually has no bell; signals are received on the bell of the terminal set, and if the user of the extension set is wanted, he is notified by a separate signal, such as a buzzer, operated by the person who answered the terminal set. Any number of extension sets may be bridged to a line. Any one of them may make a call. None can receive a call direct from the central office nor from another station on the line unless equipped with a ringer, and not then from other stations on the line unless they are magneto sets.

PARTY LINE CIRCUITS. — Party line sets differ from individual line sets only in methods of signaling. The apparatus used and the method of connecting up depends upon whether the party lines are to be non-selective or selective.

Non-Selective Party Lines. — On such lines a call made by any party on the line operates the ringers at all stations. Each station has a particular group of periods of bell ringing, which group only it is meant to answer. Up to five stations from one to five short rings per station serve well. Beyond five, long and short rings are combined. Magneto sets, both series and bridging, are used on non-selective party lines. The generator of the magneto set at any station can ring all the bells of the line at once, and operate the central office signal also, if the line leads to a central office. The bridging system is so used on many private lines, farmers' co-operative lines, rural toll lines, and, to a degree, on exchange party lines in towns.

Non-selective stations should not answer other calls than their own; this extra listening on lines is an extra drain on local batteries in sets having them; it also destroys privacy. A receiver off the hook impairs signals unless circuits are specialized.

If a condenser of low capacity, say one-half microfarad, be placed in series with the receiver, it will obstruct ringing current (frequency 20 per second) considerably, but voice currents (mean frequency 800 per second) very little.

Selective Party Lines are equipped with ringers arranged to respond each to its own call, the others remaining silent. There are three such methods in use in the United States, and still a fourth method, which has certain very decided advantages, is coming into use.

Metallic Circuit Two Party Lines (Fig. 20.) — On metallic circuits selective two party working is simple. Fig. 20 is the standard system of the

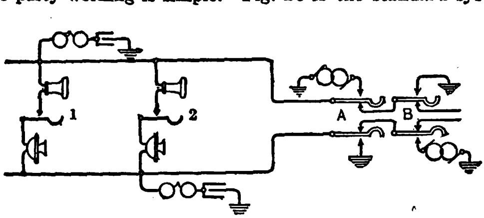

Fig. 20. Two Party System

Associated Bell Telephone Companies in the United States. Each wire of the metallic circuit is used as a private grounded ringing circuit to one station, and the pair of wires is used as a talking circuit by each station. Key *A* connects the ringing generator to the upper wire, ringing station No. 1; key *B* rings

station No. 2. If a station answers while being rung, the other station is not rung falsely, the ground on the non-ringing side of the used key preventing that.

Harmonic Selective Systems (Fig. 21) operate on the principle that a ringer having a spring-supported armature will ring for one frequency of current but not for any other frequency. Frequencies of 16, 33, 50 and 66 per

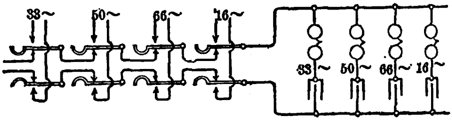

Fig. 21. Four-party Harmonic System

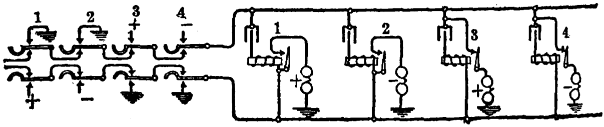
second are used in the Dean four-party harmonic system. Each calling cord in the central office switchboard can be rung upon by one of four keys, as in Fig. 21. The ringers are alike except as to the sizes of tappers, which are cylinders of metal, heaviest for the lowest frequency and graduating to lightest for the highest frequency.

The number of selective stations may be made twice the number of frequencies by connecting harmonic ringers from each wire to ground as in Fig. 20, instead of across the line as in Fig. 21. This enables eight stations to be placed on a line leading to a four-frequency central office.

Biased Ringer Systems (Fig. 22). — The Hibbard party line system uses unidirectional pulsating current for the selection of biased ringers on four-party lines. An improvement on that system (Fig. 22) is used by the American Telephone & Telegraph Company. A biased ringer is an ordinary ringer which has its armature drawn to one side by a spring. Impulses of current



• Fig. 22. Four-party Biased Bell System

in one direction only will operate the ringer. Condensers permanently in series with such ringers would interfere with the selective action; but condensers are necessary to prevent ringer connections from interfering with other functions of common battery lines. In common battery systems, therefore, a relay at each station, as in Fig. 22, connects the ringer to the proper line wire only during ringing. The same current that operates the ringer draws up the ringer relay.

Step-by-Step Party Line Systems select the desired subscriber by the operation one after another of a set of switches at the subscriber's station, controlled from the central office. Step-by-step party line systems have not come into wide use, but the development of automatic switching systems for central office use is increasing knowledge, faith and skill concerning step-by-step mechanisms.

Semi-Selective Party Lines. — Semi-selective ringing is done for more than two stations on a line, as in Fig. 20, by connecting more than one ringer to each wire, ringing code signals on key *A* for the ringers on the upper wire and ringing code signals on key *B* for ringers on the lower wire of the figure.

CENTRAL OFFICE EQUIPMENT. — Telephones are used in two general ways: (1) On a line permanently connecting two or more telephones, this line not being connectible to another, and, (2) On a line carrying one or more telephones, this line being connectible at will to any other of a group of lines. In the second case a switchboard and the necessary adjuncts for producing the various kinds of current required must be provided for connecting any line to any other. Such a switchboard and its adjuncts make up a "central office." A "telephone exchange" is an organization of one or more central offices and the connecting lines and apparatus employed in supplying telephone service to a community. A central office is, therefore, but part of an exchange.

A "manual switchboard" is one in which a human operator connects and disconnects the lines by hand, as instructed by the subscribers through signals and speech. An "automatic switchboard" is one in which machines connect and disconnect the lines in response to electrical changes in the calling line. The functions of manual and automatic switchboards sometimes are combined and named "semi-automatic systems" or "automanual systems."

A switchboard designed to interconnect telephone sets equipped with local batteries and magnetos is called a "magneto switchboard," while a board designed to interconnect telephone sets supplied with current from a single battery in the central office is called a "common battery switchboard." When each of the lines entering a central office is permanently connected to a single "jack" or terminal, the board is called a "simple switchboard." When each line is permanently connected to a plurality of jacks, located at different parts of the board, the board is called a "multiple switchboard." A multiple switchboard is divided into sections, each section accommodating three operators, and containing a jack for each line entering the central office. The group of jacks in each section is referred to as the "multiple." "Simple switchboards" can be used only in case the number of lines connected to the central office is small (less than about 300), unless local trunking in the central office is resorted to. It should be noted that the cost per subscriber of central office switchboard equipment increases as the number of subscribers increases when the total number of subscribers is sufficient to require the use of multiple switchboards.

Cords, Plugs, Jacks and Drops. — As principally used, manual switchboards connect lines by means of flexible conducting "cords" tipped with plugs which fit line-terminal-sockets called jacks. The plug contains some number of parts, electrically insulated from each other but connected to conducting strands of the cord terminating in the plug. There are two strands in the cords of simple magneto switchboards, and therefore two parts in the plug to connect to two conductors of the jack. Fig. 23 shows a jack and plug for a two-stand cord. Few switchboards involve circuits calling for more

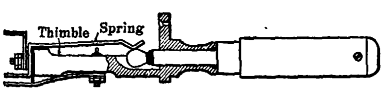


Fig. 23. Jack and Plug

Fig. 24. Diagram of Plug and Jack

than three conductors in regular switching cords. Plugs and jacks for that many conductors can be made in compact and serviceable forms. Fig. 24 shows diagrammatically a three-conductor jack and plug, in which it is intended that the tip of the plug shall engage the short spring, the ring of the plug the long spring, and the sleeve of the plug the tubular sleeve or thimble of the jack.

The cords and plugs are associated with keys, signals, wiring and current sources, and are links which the operator uses to do her work upon the lines made

accessible by the jacks. At D in Fig. 25 is shown diagrammatically the type of signal employed on magneto manual switchboards. This signal, called a "gravity drop," is bridged across the switchboard end of the line in the same manner as the ringer at the subscriber's station. When the core is energized by current from the magneto, at the subscriber's station, the armature is attracted, lifting the catch and releasing the shutter D allowing it to fall forward by gravity. These signals are called gravity drops for this reason.

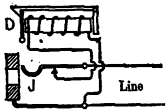

Fig. 25. Magneto Drop and Jack

Power Plants. — The power plant is an organization of devices in a central office to furnish to the lines connected to that office the several kinds of currents required. The principal elements of power plants are storage batteries, charging generators and sources of alternating current for ringing.

In the common battery system one storage battery usually supplies current to all transmitters, whether of subscribers or operators, and actuates all principal relays and lamp signals. In magneto offices storage batteries need only be large enough to supply operators' transmitters and a few auxiliary signals, as magneto equipments usually have primary batteries in subscribers' telephones.

Magneto Manual Switchboards (Figs. 25 and 26). — Fig. 25 represents diagrammatically the central office end of a subscriber's line and Fig. 26 includes the essential elements of a magneto cord circuit. Normally the tip of one plug is connected through the cord to the tip of the other, and the same is true of the plug sleeves. When a subscriber rings, the drop D in Fig. 25 falls. The central operator then inserts the plug P_1 (Fig. 26) of an idle cord circuit in the jack of this subscriber's line; this disconnects the line drop, the shutter of which is returned to its normal position either by hand or automatically. She then connects her telephone set to this cord by closing the switch A and gets the number of the subscriber wanted, and inserts the plug P_2 in the corresponding jack. By closing the switch B she connects the called subscriber's bell to the central office source of ringing current, which usually is running continuously. The called subscriber's bell rings as long as the operator presses the ringing key. When she releases it, direct connection between the two lines results. When the called subscriber answers, conversation may ensue, and at the close of it the subscribers are expected to signal for disconnection by ringing. The gravity drop D (Fig. 25), in this case called a clearing-out drop, is bridged across the cord circuit, and in response to this signal the operator removes both plugs. The line signals of both lines thus are reconnected in readiness to receive calling signals.

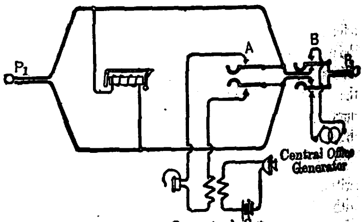

Fig. 26. Magneto Cord Circuit

The operator's set is connectible to the cord circuit by means of a key, enabling her to answer the calling subscriber by telephone, to listen to the conversation, and, by releasing one listening key and pressing another, to shift her telephone set from cord circuit to cord circuit. Depending upon a variety of conditions, an operator can utilize from ten to twenty cord circuits, transferring her telephone set from one to another as required.

In Fig. 26, ringing current can be sent out only from the right-hand plug.

Calls, therefore, are answered by using the left-hand plug of the figure, called lines being taken up by the right-hand plug. Some users require both plugs to be equipped with calling keys, in which case the left-hand plug would be given an arrangement symmetrical with that of the right-hand one.

The shutters of gravity drops used as line or clearing-out signals are restored to their upright position by hand in most simple magneto switchboards. Formerly the drops were placed in one group and the jacks in another, the drops being restored directly by the operator's fingers. Latterly the drop and jack of a line are associated together, so that the plug as inserted into the jack restores the shutter by some thrusting movement on the part of the jack. A simple way is to form a tongue upon the jack spring, this tongue thrusting the shutter directly into its latch.

Large magneto switchboards have been equipped with drops grouped at a distance from the jacks and out of reach of the operators. Such drops are restored after operation by electro-mechanical means, the act of placing the plug in the jack of a line closing circuits to restore the shutter.

Jacks are adapted to be mounted in insulating strips in whatever arrangement is desired, and any jack of a group may be dismounted. When more compact arrangement is desired, jacks are made up in strips of ten or twenty, an entire strip of which must be removed from the framework of the switchboard to enable one jack to be inspected or worked upon.

During hours of light telephone traffic, as at night, it is desirable to use as few operators as can handle the traffic satisfactorily, and, in small exchanges, even to allow the operator to sleep between calls. On a long switchboard a drop may fall many feet away from the night operator and its falling be unheard. A night alarm signal is provided by equipping each drop with a contact closed by the falling of the shutter. These contacts of all the drops of a group are wired in multiple to a battery, bell and switch which is closed at night. When any drop of that group falls, the bell will ring if the switch is closed.

Switchboard plugs, when not in use, stand vertically in a plug shelf, the cords being housed within the switchboard framework and kept reasonably taut by means of weighted pulleys. Weights should be heavy enough to enable cords to return plugs to position after disconnection, and not so heavy as to shorten unduly the lives of the flexible conductors within the cords.

Where grounded circuits are connected to metallic circuit switchboards and require interconnection with metallic circuits, a ground connection must be provided to furnish the second limb of the line, as switchboards now are built entirely for metallic circuits. Such grounds must be connected to jacks in one unvarying way or two grounded circuits may be connected so as not to be able to talk to each other. The usual practice is to connect the line wire to the spring of the jack and the ground to the sleeve.

Simple Common Battery Switchboard (Fig. 27).—The circuits of a representative simple common battery switchboard are shown in Fig. 27 and are those of the Kellogg Switchboard & Supply Company. They are a type of many other makes. The subscribers' lines terminate in cut-off jacks. There is only one jack per line. The calling plugs only are equipped with ringing keys.

The cycle of operations of such a system is as follows: The subscriber removes the receiver from the hook and as there is no plug in the jack of his line at the central office, the line relay is actuated, lighting the line lamp and operating the pilot relay. The pilot relay, in turn, lights a pilot lamp, of which there is one for a considerable number of line lamps, and with which a bell or other night alarm signal can be associated. Responsive to the lighting of the line lamp, which in practice is mounted close to the line jack, the operator inserts an answering plug in the jack, breaking the line relay circuit in two places, and so extin-

guishing the line lamp. Operating her listening key, the operator connects her talking set with the cord circuit, asks for the subscriber's order and executes it by inserting the calling plug in the jack of the line called for, unless that jack already is occupied by a plug. If it is occupied, she tells the calling subscriber

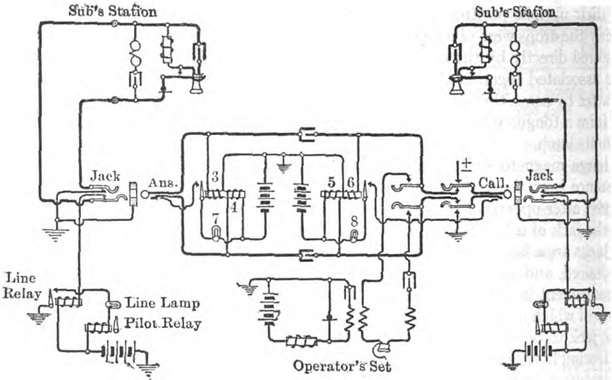

Fig. 27. Circuits of Simple Common Battery Switchboard

that the called line is busy. If it is not occupied, she plugs into it, as stated, and rings. At this stage, the supervisory lamp 7, adjacent to the answering plug, is dark and the supervisory lamp 8, adjacent to the calling plug, is lighted, indicating that the calling subscriber's receiver is off the hook and the called subscriber's receiver is on the hook. When the called subscriber answers in response to the ring, lamp 8 is extinguished. At the close of the conversation, both lamps will re-light as the respective receivers are hung up. In this way the operator can tell at all times the state of the connection and conversation and, responsive to the final lighting of both supervisory lamps, she removes both plugs with the *positive* knowledge that the conversation has been finished.

The heavy lines in Fig. 27 are those over which the subscriber's conversation takes place. In the cord circuit the two conductors which carry voice current are continuous from tip to tip and from sleeve to sleeve of the plugs, except that a condenser is interposed in each of the two conductors. Direct current to actuate subscribers' transmitters is furnished to the calling subscriber through

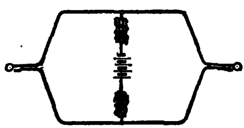

Fig. 28. Impedance Coil Cord Circuit

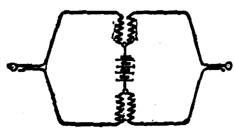

Fig. 29. Repeating Coil Cord Circuit

the windings 3–4 of the answering supervisory relay and to the called subscriber through the windings 5–6 of the other. Each supervisory relay thus serves two purposes, one being to supply the subscriber's transmitter with current, the other being to co-operate with the ground at the *line* jack so as to light the supervisory lamp if no direct current flows through the line, and to extinguish the supervisory lamp while the direct current does so flow.

There are three general ways in which direct current can be supplied from cord circuits to subscribers' lines. In Fig. 28 current is supplied through impedance coils without condensers. Such a plan is suitable where all the lines of a switchboard are of about equal resistance, as in a private exchange. If the lines are of varying resistance, a high resistance line will be denied proper current when connected through such a cord circuit to a low resistance line (low compared to the resistance of the impedance coil). The circuit of Fig. 29, using a repeating coil, is free from this objection and is standard with the American Telephone & Telegraph Company. The circuit of Fig. 30, using impedance coils and condensers, is as efficient as that of Fig. 28, though entirely different in principle. It is widely used in manual and automatic switchboards other than those of the American Telephone & Telegraph Company.

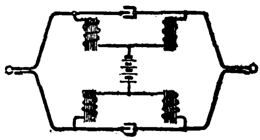

Fig. 30. Condenser Cord Circuit

Comparison of Magneto and Common Battery Systems.—The magneto system is best in small towns and country exchanges. Magneto systems are best for exchanges under 500 lines and common battery systems best above that number. No positive rule can be laid down. For example, the magneto system may be arranged in exchanges which start with little equipment and do not grow beyond 500 lines while the equipment still is in good condition. Conversely, common battery systems may be warranted in exchanges as small as 200 lines, wherein the conditions are favorable and the need of the highest grade of service is great.

Transfer Systems or Local Trunking.—When it is desired to use a simple magneto or common battery system in an office requiring more than three operators, so that there will be lines beyond the reach of each operator, it is possible to provide local trunks or transfer circuits to interconnect lines which cannot be reached directly. These are called transfer systems or local trunking systems. If an operator has a call for a line which she cannot reach directly, she inserts the calling plug in a jack of a trunk which leads to the section carrying the jack of the called line. At that section an operator connects the chosen trunk with the called line and assists in disconnecting it at the end of conversation. These systems have service disadvantages which in most cases more than outweigh the savings, and the best practice is to use multiple switchboards where simple switchboards are outgrown. An important exception is the case of large cities where the majority of calls would have to be completed through a second central office in any event. Under such circumstances multiple jacks for the trunks only are provided, the subscriber's line being provided with but a single jack and practically all calls are trunked irrespective of their designation.

Multiple Switchboards (Fig. 31).—A multiple switchboard is one in which all the lines of the office are brought within reach of each operator by equipping each line with a number of jacks, distributed over the board in such a manner that each operator can reach at least one of these jacks. The usual practice is to equip each line with one answering jack, at which all its calls will be answered, and in addition with a plurality of line jacks into any one of which a plug may be inserted when that line is called. As there is a plurality of places where the called line may be taken, some guard is required to prevent an operator taking the line when it is in use at another part of the switchboard. This guard is called the "busy test" and is provided by changing the electrical state of a metal thimble of each jack of a line whenever a plug is inserted. When idle, all the thimbles of all the jacks of a line are at the same potential as all the tips

of all idle plugs. Touching the tip of a plug to the sleeve of a jack of an idle line produces no electrical result. But when an operator touches the tip of a plug to the sleeve of a line which is busy, difference of potential between tip and sleeve causes current to flow and a click to be audible in her receiver. She then tells the calling subscriber the called line is busy.

Fig. 31 shows the complete circuits of a calling line, a called line, and the connecting cords of the Western Electric Company's relay switchboard No. 1,

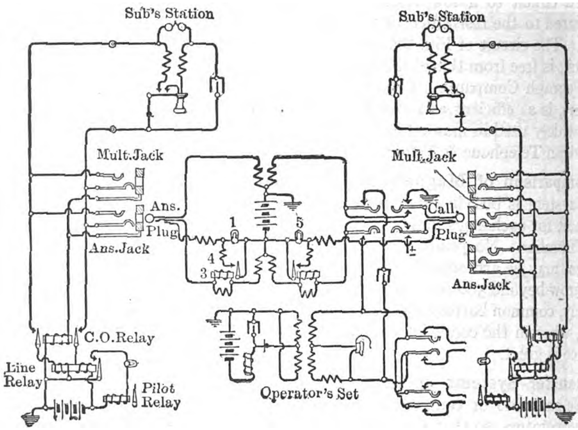

Fig. 31. Circuits of Multiple Battery Switchboard

which is the standard of the American Telephone & Telegraph Company. The cycle of operations is exactly as described with reference to the simple common battery switchboard with the addition of testing the jack of the called line. Current supply to the cord circuit is of the form shown in Fig. 29. The jacks have fewer parts than in the simple switchboard before described. The line relay is disconnected from the line by a cut-off relay instead of by a cut-off jack. The cut-off relay is operated by current from the cord circuit when a plug is placed in any jack of the line. This current also furnishes the busy test potential to all jacks of a line so long as a plug is in any jack. Direct current which actuates the subscriber's transmitter also energizes the relay 3, placing the shunt 4 around the supervisory lamp 1. It results that the lamp 1 or 5 will be lighted or dark, depending upon whether the switchhook of its line is down or up.

All principal common battery multiple switchboard systems now in general use have the common features of an audible busy test, line lamp signals, two supervisory signals per cord circuit — one for each line of a connection — and answering jacks supplementing the multiple (or calling) jacks. None of them requires more than two wires in the subscriber's line outside of the central office, but the system of Fig. 31 requires three wires in the line throughout the switchboard. Other systems require only two wires throughout the switchboard and in these systems the busy test and cut-off relay functions are combined with the other functions of one of the wires of the line. The advantages of the two-wire over the three-wire system lie principally in the greater simplicity of the jacks and the fewer wires necessary in the switchboard cables.

Common battery multiple switchboards for use in offices of from 500 to 1200 lines sometimes are provided with cut-off jacks, avoiding the necessity of using cut-off relays. Some such switchboards use magnetic mechanical signals as a substitute for lamp signals. They are not the best practice. Lamp signals have decided advantages. They are compact, can be mounted closely adjacent to jacks, show great contrast between actuated and non-actuated condition, and are not easily obscured by cords.

A and B Operators. — Manual multiple switchboards are adapted to bring all the lines of the office within reach of each operator, but such switchboards cannot concentrate more than 10,000 lines within such reach unless the jacks are made smaller than is considered the best practice. When an exchange contains more than 10,000 lines, it is customary to provide more than one office. This makes possible a saving in lines and things relative to them, but requires calls to be trunked from one office to another. In an exchange of 100,000 lines, for example, there would be ten switchboards of 10,000 lines each, each switchboard serving a district of the exchange.

Calls *originating* in one district will be *for* lines in all the districts and only those for lines in the originating district can be completed in the switchboard for that district. Calls for subscribers in all the nine other districts must be trunked. To accomplish this, the operators in a multi-office exchange have equipment enabling them not only to complete calls directly in the multiple before them but to connect subscribers with trunk lines leading to the other offices, and in each office furthermore there are operators and equipments adapted to receive and complete calls trunked to them from the offices where they originated.

Operators who answer subscribers are called *A* operators; operators who serve trunk lines incoming from other offices are called *B* operators. The cycle of operations in a call for a line not in the office first called is as follows: subscriber lifts his receiver and his line lamp lights; operator answers and asks number; learning by prefix that call is for a subscriber in a distant office, operator presses a key marked with that prefix, so connecting her telephone set with a line leading directly to a receiver of a *B* operator in the distant office; *A* operator speaks the number desired, following with the *prefix of her own office; B* operator in distant office names back a trunk number; *A* operator inserts calling plug in a multiple jack of that trunk and simultaneously distant *B* operator inserts the plug of that trunk in the called line; method of ringing depends on type of apparatus; at close of conversation *A* operator disconnects, which act lights disconnect lamp before *B* operator, who disconnects in response, extinguishing signal.

Main Distributing Frame. — The main distributing frame is a device upon which are terminated, usually upon opposite sides, the lines from subscribers and from switchboard apparatus. Between these terminals connecting links of wire, called "jumpers," are soldered. The purpose of the main distributing frame is to enable a subscriber's line to be connected semipermanently with a given switchboard line. A subscriber may move anywhere within the district of his central office and may utilize any pair of wires entering that office without relinquishing his particular telephone number, as his switchboard circuit may be connected by jumper to whatever entering cable wires his line may use. Protective apparatus, consisting of sneak current arresters and carbon air-gap arresters, is associated with all lines entering a central office. These protective devices customarily are mounted on the switchboard side of the main distributing frame.

Intermediate Distributing Frame. — The intermediate distributing frame is a device on which lines to multiple jacks and lines to answering jacks

respectively are accessible for inter-connection. Its object is to enable a given line to terminate on an answering jack at any part of the switchboard and this connection also is semi-permanent. By this is meant that when a subscriber's line has been connected by jumper to an answering jack on a certain operating position, all the calls of that line will be answered at that position until the jumper in the intermediate distributing frame has been changed. The purpose is to enable the traffic originated by the subscribers of an office to be divided equally among the operators. This equalization is not automatically done by the intermediate distributing frame, as is the intent in the automanual system.

Automatic Switchboards.—An automatic switchboard is a set of machines in a central office, adapted to connect and disconnect lines under the control of subscribers. These machines do automatically what human operators do on manual switchboards. The objects are to save the cost of the labor of manual operators and to increase the speed and accuracy of connecting and disconnecting. As the only human operating which is done in an automatic system is done by the subscribers themselves, the accuracy of connecting depends on the skill of the subscribers. In practice this is found to be sufficiently high for the rendering of good service. Automatic systems have the considerable advantage that the disconnection of the lines is instantaneous, which is not true in any purely manual system.

Automatic systems are in successful use in many exchanges in the United States and in a few elsewhere. The apparatus is more intricate than that of manual switchboards. The first cost of automatic equipment is greater than manual equipment in small systems and less in large systems. In both manual and automatic systems the larger the traffic the more equipment per subscriber is required in the central office and the greater is its cost.

All automatic systems so far devised utilize the step-by-step principle. In the system of the Automatic Electric Company, which now is in wide use, selector and connector switches take as many steps per movement as there are units in the digit called.

In manual multiple switchboards, all the lines of an office are accessible to each operator. At the time of making a connection the operator and the calling plug of a cord circuit may be considered as a terminal device attached to the calling line and seeking the called line in the multiple of all the lines. In a manual transfer switchboard or in the trunking of a call from one office to another in an exchange having several offices with multiple switchboards, a first and a second operator must co-operate to complete certain connections.

An automatic system represents a third case in which two or more devices must co-operate to complete a connection. In a word, as many separate machines are engaged in making a connection as there are digits in the called number, less one.

Success in automatic telephony came with the abandonment of the complete multiple principle and the adoption of the complete trunking principle, which had been abandoned in manual telephony some time before.

Selector and Connector Switches. — The underlying feature of the automatic trunking system is that the calling subscriber directs the first "selector switch" to seek an idle trunk from a certain group of trunks, all of which lead in a direction determined by the first digit of the called number. This first switch makes as many vertical steps as there are units in the first digit called, and immediately thereafter seeks out and appropriates an idle trunk of that group. On the calling of the next digit, a switch at the end of this selected trunk takes as many vertical steps as there are units in the second digit, and immediately seeks out and appropriates an idle trunk in that group. This process is repeated until all but two digits have been called, which carries

the connection to the last switch which will be used. This switch is called a "connector" and has vertical and rotary motions like the preceding switches, but, unlike them, both vertical and rotary motions are under the subscriber's control. As he calls the next to the last (tens) digit, the switch takes as many vertical steps as there are units in that digit but does not follow with an automatic rotation. It rotates in response to the calling of the last digit, taking as many steps as there are units in that digit and stopping with its wipers in contact with terminals of the called line. Ringing of the called subscriber then is caused by automatic means or by relays responsive to a push button in the calling subscriber's telephone. Disconnection ensues when the calling subscriber hangs up his receiver.

Space does not permit a detailed description herein of the circuit connections for an automatic system.

Semi-automatic Switchboards. — There have been many proposals to introduce automatic switches into manual systems to do certain things better or more cheaply than in complete manual systems. Some of these proposals arrange to distribute incoming calls among operators, the remainder of the process being the same as in a standard multiple manual switchboard. Other proposals arrange to substitute automatic switches for the multiple switchboards with or without any arrangement for distributing the incoming traffic upon the operators.

Both plans have advantages, a chief one being the instantaneous disconnection which is possible with automatic devices. Another is that an automatic system is fundamentally a trunking system and the tendency of growth in exchanges is more and more toward large percentages of trunking. A principal office in New York City, for example, completed 80 per cent of the calls of its subscribers directly in its own multiple twenty years ago, 25 per cent ten years ago, and completes perhaps 5 per cent now. In other words, of the calls of its subscribers the percentage trunked to other offices has risen from 20 per cent of the total to 95 per cent of the total in twenty years. Under such circumstances, it no longer is considered good practice to provide any multiple of subscribers' lines in switchboards which handle calls from subscribers but to trunk all calls whatever may be their destination. Automatic apparatus is particularly adapted to this work.

Automanual System. — The automanual system is an example of semi-automatic systems and is in use in several exchanges in the United States. It consists of a group of automatic switches controlled by keys before an operator. She receives calls orally from subscribers and completes connections by touching a key for each digit called. The automatic apparatus finds and calls the desired line and disconnects the lines when conversation ends. Operators of this system are able to handle several times as many calls per day as in regular manual systems. One operator is reported as having completed 1100 connections in one hour.

PRIVATE EXCHANGES. — A private exchange is a group of telephone lines and switching apparatus subordinate to a central office, and usually on the premises and for the uses of a single business. Private exchanges are widely used in hotels, apartment houses, factories and suites of offices.

Private exchanges are of three types: those using simple switchboards which are attended by operators through whom all local and outside calls pass; those requiring keys at each telephone whereby each user may select the line of any local telephone or a trunk line to a central office, and those having a local equipment of automatic switches. The latter systems usually are connected to automatic central offices.

In all cases the object of the private exchange is to enable the telephones

within them to communicate with each other directly without using lines through the central office at all. A second object is to enable communication from telephones of the private exchange through the central office by the use of fewer trunk lines than there are telephones in the private group. A serviceable ratio of trunk lines to local telephones may be from one-tenth to one-fifth, at a considerable saving in cost over the providing of a line to the central office from each local telephone.

PHANTOM CIRCUITS (Fig. 32.)—In Fig. 32, four wires join two offices. *RR* are transformers with their secondaries arranged as repeating coils. They are designed to be efficient in transforming both talking and ringing currents. Currents from telephones connected to either physical pair of wires pass at any instant in opposite directions in the two wires of the pair. The phantom circuit uses one of the physical pairs as a wire of its line. It does this by tapping the

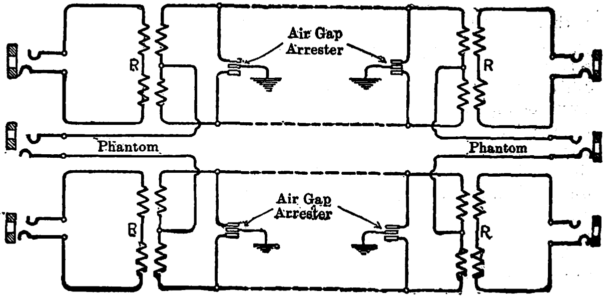

Fig. 32. Phantom Circuits

middle point of the line side of each of the transformers. The currents of the phantom circuit are not heard in the physical circuit because they pass outwardly from the middle points of the secondaries in equal and simultaneous amounts and, therefore, produce no resultant magnetization in the core. The currents of the physical circuits are not heard in the phantom circuit because the former can produce no differences of potential in the phantom circuits, provided all four wires are equal in resistance and insulation; under these conditions no difference of potential can exist between the middle points of the repeating coils at the two ends of the line.

JOINT TELEPHONE AND TELEGRAPH CIRCUITS.—Telephone lines may be equipped so as to permit speech and telegraphy to go on over the same wires at the same time without interference with each other. There are two ways of accomplishing this, being known respectively as the simplex system and the composite system.

Simplex Circuits (Fig. 33) are made from metallic circuit telephone lines as in Fig. 33. The principle is the same as that of a phantom telephone circuit. Nearly the same results can be obtained by using a simple impedance coil (i.e., a single winding with tap brought out from the center) bridged across the telephone line instead of a transformer inserted in it, but in ringing on such a line with a grounded generator the telegraph relays will chatter.

Composite Circuits (Fig. 34) depend upon a different principle. Impedance coils are inserted to oppose alternating currents, and condensers to oppose direct currents. In Fig. 34 one telephone circuit forms two Morse circuits, so

that two wires form one telephone circuit and (with the earth) two telegraph circuits. Each Morse circuit includes in series two 50-ohm impedance coils and condensers are shunted to ground between the Morse sets and the impedance

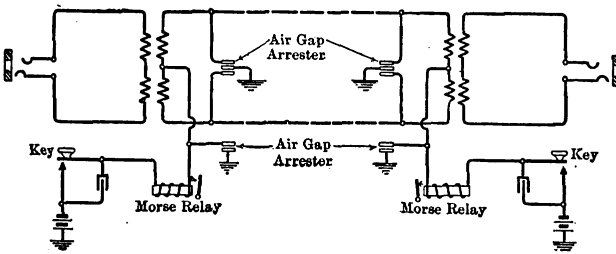

Fig. 33. Simplex Telephone and Telegraph Circuit

coils. The 50-ohm impedance coils are connected differentially and so offer low impedance to the Morse impulses, whose frequency is not high. The coils, however, offer great impedance to voice currents, since they are not differentially connected with respect to the latter. Voice currents can pass through the con-

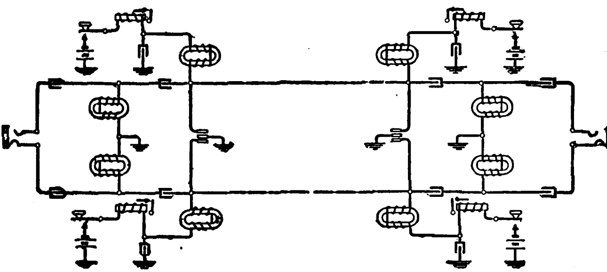

Fig. 34. Composite Telephone and Telegraph Circuit

densers in the telephone line, but direct currents cannot. Impulses due to discharge of coils and capacities in the Morse circuit would make sounds in the telephone but that they are choked off or led off by the 30-ohm impedance coils and the large capacities connected to the Morse sets.

Railway Composite Systems. — The principles of the respective impedances of inductances and capacities to direct and alternating currents, upon which the composite system depends, are applied to the conversion of series telegraph lines into combined telegraph and telephone lines. It sometimes is of advantage to modify a single-wire telegraph line so that telephones may be worked upon it, without abandoning its use as a regular telegraph circuit.

Such an arrangement is known as a railway composite system. Calls between telephone stations on such a circuit are sent by means of high-frequency alternating currents, such as are developed, for example, in an automobile spark coil. The signals are received at the telephone stations on "howlers," which are merely telephone receivers with special horn-shaped mouthpieces. These calling currents are of such high frequency as not to affect the telegraph relays. The paths for the higher-frequency currents in general are supplied by condensers and the

paths for the lower-frequency currents for telegraphy in general are supplied by inductance.

COSTS. — The following prices were current in 1913; they are all f.o.b. factory. These costs are given merely as a rough guide for preliminary estimates. For accurate estimates quotations should be obtained from the manufacturers.

Magneto wall set complete: —	
Series (80-ohm ringer)	$9.00
Bridging (1000- to 2500-ohm ringer)	10.50- 12.25
Magneto desk set complete: —	
Add 75 cents to above prices.	
Common battery wall set complete: —	
Oak or walnut, 500-ohm ringer	8.50
Oak or walnut, 1000-ohm ringer	8.75
Hotel type, 1000-ohm ringer	7.25
Common battery desk set complete with cord: —	
500-ohm ringer	9.25
1000-ohm ringer	9.50
Automatic wall or desk set	13.00
Magneto switchboards: —	
50–200 lines, 1-operator equipment	175–575
250–300 lines, 2-operator equipment	730–865
Simple common battery switchboards: —	
100–600 lines	550–2500
Corresponding cost per line	5.50–4.17
Multiple common battery switchboards: —	
1000–13,000 lines, 160 multiple jacks per position, with power plant	13,000–280,000
Corresponding cost per line	13.50–21.50
Power plants: —	
200 to 1000 lines	200–575

[S. G. McMeen.]

TELEPHONE LINES. — (*See also Distribution Lines; Transmission Lines; Wires and Cables.*) The line always consists of two conductors, though one of these may be the earth. The standard telephone line consists of two wires of the same size and of the same material. If only one wire is used and the earth forms the return the line is called a "grounded circuit." A line of two wires without earth return is called a "metallic circuit."

LINE CONSTANTS. —(*See also Transmission Lines.*) The transmitting efficiency of a telephone line depends upon its resistance, electrostatic capacity, leakage and inductance.

Leakage. — High insulation, i.e., small leakage, between the two wires of a line and from each wire to earth is possible in cables, and reasonably high insulation is possible in open wire lines. Porcelain insulators in open wire give higher insulation of open wire lines than do glass insulators.

Resistance. — The resistance of the conductors of a line attenuates the telephone current, but does not distort it appreciably, because the losses due to resistance are practically independent of the frequency of the current.

Electrostatic Capacity. — The electrostatic capacity of a line attenuates the current and distorts it also, because the charging current is not independent of the frequency. As the voice current is an alternating one of composite frequency, the higher frequencies are reduced more than the lower. There are two ways of expressing the important and controlling quantity of capacity in cables, i.e., in terms of the "mutual capacity" of the two wires or in terms of the "grounded" or "regular capacity." (*See article on Capacity and Charging Current.*) The mutual expression is the better because it is the amount of mutual capacity which determines the capacity losses. Mutual capacity in telephone cables is about two-thirds the regular capacity of the same wires. A given cable has higher capacity at high temperatures and cable capacities should be referred to a standard temperature in specifying.

Inductance. — The inductance of telephone lines is usually comparatively small, since the wires are usually close together. Insulated wires twisted together for use as lines in cables have very small inductance. (*See article on Inductance and Inductive Reactance.*)

Pupin Coils. — In 1887 Oliver Heaviside pointed out that an increase of inductance would decrease the harmful effects of capacity. In 1900 Prof. M. I. Pupin made public (*Trans. A.I.E.E., Vol. XVII, p. 445*) his method of reducing attenuation and distortion by inserting additional inductance into lines and showed how to determine how much inductance to insert and where. In an ideal method, distributed inductance would offset or neutralize the distributed capacity. In the Pupin method the inductance is inserted in the form of coils at predetermined intervals. The coils ordinarily are a mile or more apart.

CHARACTERISTICS OF OPEN WIRE LINES. — For open wire aerial lines hard drawn copper is now almost universally used, except for short unimportant lines, where iron wire may be employed. The sizes of copper wire employed range from No. 16 B. & S. to No. 8 B. & S., depending upon the length and importance of the line. Where the tensile strength of the wires is unimportant, as when the wires are fastened along walls or fences, with supports close together, smaller sizes may be employed, and soft drawn wire used instead of hard drawn. Aerial wires are usually spaced about a foot apart, horizontally, and from 18 to 24 inches vertically, depending upon the spacing of the cross arms. For the resistance, capacity, and inductance of aerial wires see *Wires and Cables, Bare.* The insulation resistance between a pair of aerial wires depends upon the types of insulator, pin and cross arm, and upon the

condition of the weather. The following values are representative of good practice: —

Very dry,	500 megohms per mile.
Average,	25 megohms per mile.
Very wet,	2 megohms per mile.

Three different gages are employed for specifying the size of telephone wire: the B. & S., the B. W. G., and the N. B. S. (*See article on Gages, Wire.*) The following table gives the diameter, weight and resistance of the various sizes employed in telephone practice.

TABLE I

Number	Diameter in mils	Weight per mile in pounds	Resistance per mile of wire in ohms, 60° F.	Resistance per mile of circuit in ohms, 60° F.
8 B. W. G.	165	435	1.97	3.95
6 B. & S. G.	162	419	2.05	4.10
8 N. B. S. G.	160	409	2.10	4.20
9 B. W. G.	148	350	2.45	4.91
7 B. & S. G.	144.3	331	2.59	5.19
9 N. B. S. G.	144	331	2.59	5.19
10 B. W. G.	134	287	2.98	5.97
8 B. & S. G.	128.5	262	3.28	6.56
10 N. B. S. G.	128	262	3.28	6.56
11 B. W. G.	120	230	3.73	7.47
11 N. B. S. G.	116	215	3.99	7.99
9 B. & S. G.	114.4	208	4.14	8.27
12 B. W. G.	109	190	4.52	9.05
12 N. B. S. G.	104	173	4.97	9.94
10 B. & S. G.	101.9	166	5.17	10.33
13 B. W. G.	95	144	5.96	11.91
13 N. B. S. G.	92	135	6.35	12.70
11 B. & S. G.	90.74	132	6.49	12.98
14 B. W. G.	83	110	7.80	15.61
12 B. & S. G.	80.81	105	8.19	16.39
14 N. B. S. G.	80	102	8.40	16.80

CHARACTERISTICS OF TELEPHONE CABLES. — Telephone cables are groups of pairs of paper insulated wire twisted together and enclosed in a lead sheath. Soft drawn copper is invariably used for the conductors. The size wire usually employed ranges from No. 19 to No. 22 B. & S. For long distance underground lines individual wires as large as No. 10 B. & S. have been employed. For the resistance of the different sizes of conductors see *Wires and Cables*. The capacity of any pair of wires and the capacity of any one wire to ground depends largely upon the way in which the cable is made up. When the wires are twisted tightly together the capacity is greater than when they are loosely assembled. The mutual capacity ranges from 0.067 to 0.090 microfarad per mile, and the regular or grounded capacity from 0.10 to 0.12

microfarad per mile for tightly twisted wires, as against 0.054 to 0.067 and 0.080 to 0.10 respectively for loosely twisted wires. The former range of capacity is usually referred to as "high" and the latter as "low" capacity.

The effective insulation resistance between the two wires of a pair is about ½ megohm per mile at 800 cycles per second in a well-constructed cable. This figure includes the effect of dielectric hysteresis. The corresponding insulation resistance measured by direct current would be about 500 to 1000 megohms per mile.

The inductance of a pair of wires in a telephone cable is practically negligible, being less than 1 millihenry per mile of cable (2 miles of wire).

DISTORTION AND ATTENUATION. — (*See also Transmission Lines.*) Corresponding to any vowel, syllable or word spoken into a transmitter a current wave of a definite shape is sent over the line. This wave is made up of a number of simple sine waves of different frequencies, called harmonics, displaced with reference to one another, i.e., reaching their zero values at different times. Each of the simple sine waves as it progresses along the line decreases in amplitude or is "attenuated." Moreover, the shorter waves are in general attenuated more than the longer ones, with the result that the wave which reaches the receiver is made up of harmonics of relatively different magnitudes than the wave sent out from the transmitter, that is, the resultant wave at the receiver is "distorted." The sound produced by the receiver, consequently, differs from the word spoken into the transmitter, since the quality of the sound depends upon the relative magnitude of the constituent harmonics. There is also a displacement of the harmonics with reference to each other, which displacement, although it changes the shape of the resultant wave, has but little, if any, effect upon the quality of the sound.

Attenuation of a wave without distortion merely changes its amplitude, but since the wave form remains unchanged, only the loudness of the sound produced thereby, were it converted into a sound wave, is affected. Resistance alone, since it produces the same relative attenuation of all wave lengths, is therefore the least troublesome of the line characteristics. In most cases, the capacity of the line is the controlling characteristic, since the attenuation produced thereby depends upon the wave length, and therefore distortion results.

In addition to the distortion produced by the line itself, there is also a distortion in the transformation at the transmitter of the sound wave into a current wave, and again another distortion at the receiver where the current wave is reconverted into a sound wave.

DISTURBANCES DUE TO NEIGHBORING POWER TRANSMISSION LINES.* — (*See also Distribution Lines; Transmission Lines.*) A very small voltage between the wires of the telephone circuit is sufficient to produce noise in the telephone apparatus comparable in volume with the sound produced by the voice currents. The noise is due almost entirely to the harmonics of the power system, especially to those between 150 and 1200 cycles. At these frequencies induced currents in the telephone line equal to a few millionths of an ampere are sufficient to make conversation difficult.

Balanced versus Unbalanced Power Circuits. —In considering the effect of neighboring power circuits on telephone circuits the difference between balanced and unbalanced power circuits must be clearly kept in mind. A *completely balanced* power circuit consists of two or more wires energized in such a way that the vector sum of the currents in all the wires of the circuit is practically zero, and the vector sum of the voltages between the several wires and the ground is practically zero. A *completely unbalanced* power circuit consists of one or more wires with a ground return, the currents in all the wires being practi-

* By H. Pender.

cally in phase and the voltages between the several wires and the ground being practically equal and in phase. In practice power circuits are frequently neither completely balanced nor completely unbalanced, but the currents and voltages may be resolved into completely balanced and completely unbalanced components. Examples of such circuits are a three-phase circuit having one wire grounded and a three-phase circuit with grounded neutral; in the latter case the neutral current may be of fundamental frequency due to an unbalanced load on the system, or the neutral current may be of triple frequency due to a third harmonic in the voltage wave (*see Generators, Alternating Current*).

The inductive effects arising from unbalanced voltages or currents are very much larger than the inductive effects arising from balanced voltages or currents of the same magnitude, because with balanced voltages and currents the effect of one wire is largely neutralized by the near presence of other wires of opposite polarity.

Voltages Induced between Wires and between Wires and Ground. — The power circuits affect the telephone circuits by producing: (1) a voltage between the two wires of the telephone circuit; (2) a voltage between telephone wires and ground.

The voltage between telephone wires and ground is usually large compared with the voltage between wires. Even though the telephone circuit is transposed so that equal voltages are induced between the two wires and ground, the voltage to ground produces a voltage between wires because of the unavoidable minute inequalities in the constants of the two sides of the circuit. If the voltage to ground is high it endangers the users and operators of telephones connected to the circuits and puts the circuits out of commission by operating the protective devices.

Remedies for Inductive Disturbances in Telephone Lines. — It is in practice impossible to perfectly realize any of the following remedies, and no one of them would be sufficient even though perfectly realized. In order to minimize inductive disturbances it is therefore necessary to carry out each of the remedies as far as possible.

1. **Transposition of Power and Telephone Circuits.** — The way in which inductive effects are affected by the transposition of the power and telephone circuits is indicated in the following table:

EFFECT OF TRANSPOSITIONS

Power Line	Voltages Induced in Telephone Line	Affected by Transpositions in	
		Power Circuit	Telephone Circuit
Balanced	To ground	Yes	No
	Between wires	Yes	Yes
Unbalanced	To ground	No	No
	Between wires	No	Yes

In order to balance as far as possible the inductive effects between a three-phase power circuit and a telephone circuit it is necessary to divide each uniform section of the exposure into six or a multiple of six equal sections in which equal voltages of the six possible phase angles are induced. The methods of making transpositions of a telephone line are described below in the section on *Line Construction;* methods of transposing power lines are described in the article on *Transmission Lines*.

2. **Balancing the Power Circuit.** — The voltages induced between the telephone circuits and ground by small unbalanced components of the power voltages and currents are relatively large and are not affected by transpositions. In order to reduce the inductive interference, it is therefore important to construct and operate the power circuit in such a way that it is as far as possible balanced with respect both to voltage and to current.

3. **Balancing the Telephone Circuit.** — In order that the noise caused by the voltage between the telephone wires and ground may be minimized, it is necessary that the telephone circuits be carefully balanced, that is, that the two sides of the circuit be of the same resistance and have as nearly as possible the same insulation resistance and the same capacity to ground. The unbalancing due to unequal insulation and to unequal capacities between cable conductors and ground is frequently important and every effort should be made to minimize it. All apparatus connected to the circuit must be such that the impedances inserted in the two sides of the circuit, or the impedances connected between the two sides of the circuit and ground, are as nearly as possible exactly equal.

COMMERCIAL TRANSMISSION. — LIMITING TRANSMISSION DISTANCES. — Transmission is said to be "commercial" when two persons with normal ears and voices, using standard transmitters and receivers, can converse with reasonable ease. The length of the line over which such a conversation can take place is called the "limiting transmission distance." The limiting transmission distance of a pair of No. 19 B. & S. copper wires in a paper insulated cable is about 30 miles, the resistance per mile of cable or "loop mile" (2 miles of wire) being 88 ohms and the mutual capacity of the two wires 0.06 microfarad per mile. Such a line is taken as a standard to which all other lines may be referred.

For ease in comparing various lines, the qualities of the standard line just described are very closely imitated by assembling resistance coils and condensers in a portable case, the number of coils and condensers being such that the artificial line thus made is equivalent to many miles of the standard line. This artificial line is usually referred to as a standard cable set.

To determine the qualities of an unknown line in terms of standard cable, an observer listens to a distant speaker alternately through the unknown line and the standard cable set. He adjusts the latter until he hears the speech equally and similarly through both. The number of miles of the standard set then gives the limiting transmission distance of the line tested. The quotient of the limiting transmission distance by the actual length of the line is a measure of its transmitting ability.

The limiting transmission distances of various types of lines determined in the manner explained above are given in Table II, below. This table includes no allowance for switchboard and connection losses.

Effect of Bridging Telephone Set Across Line. — The effect of bridging a standard local telephone set across a non-loaded open-wire line is to diminish the limiting transmission distance by approximately 12 per cent. The loss due to bridging such a set across a cable circuit is considerably less, namely, about 7 per cent. These figures also apply roughly to each of several sets bridged across the line, provided these sets are widely separated.

LINE CONSTRUCTION. — In open country and small towns aerial lines with bare wires are almost invariably used. In large cities cables containing from 5 to 600 pairs of wires are usually employed. Cables may be run overhead or underground. Aerial telephone cables, on account of their low tensile strength, are hung from steel messenger wires, the latter being supported from the cross

TABLE II

Gage of wire	Theoretical limiting distance, with no allowance for switchboard losses and without Pupin coils
	Miles

10 B. W. G. iron, open wire line	120
12 B. W. G., iron, open wire line	90
16 B. & S. cable, copper	40
19 B. & S. cable, copper	30
22 B. & S. cable, copper	20

Wires smaller than those given in this table should not be used on pole lines, on account of their lack of mechanical strength.

arms or fastened directly to the poles. Underground cables are usually run in tile or other type of ducts. (*See Conduits and Conduit Lines, Underground; Wires and Cables.*)

Open Wire Lines.—With the exception of the smaller insulators, usually glass, and the larger number of wires carried on a single pole line (as many as 100), the construction of open wire telephone lines differs but slightly from that of pole lines for power transmission. (*See Cross Arms; Distribution Circuits; Poles for Overhead Lines; Transmission Lines.*)

The size of poles and their spacing usually employed for various classes of lines through level country are given in the following table:

Type of line	Ultimate number of wires	Height, feet	Diameter of top, inches	Number per mile
Short, local	6	22	5 to 6	30
Important routes	20	25	6 to 7	40
Long distance	30 to 40	30 to 35	7 to 8	40

Where special conditions arise the height and size of poles must be selected accordingly. The depth to which a pole is set in the ground ranges from one-fifth to one-eighth of its total height, the larger figure applying to short poles (25 feet), the latter to tall poles (65 feet).

Hard drawn copper wire is now used on all important lines, though galvanized iron wire is still employed on short unimportant lines. Recently copper-clad steel wire has been proposed for telephone lines. See *Wires and Cables* for the properties of wires. The particular size to be employed in any case will depend upon the length of the line; see Table II above. In open wire lines the wires are usually spaced one foot apart horizontally and the cross arms are spaced 18 to 24 inches apart.

Transpositions to Prevent Cross-Talk. — Any varying magnetic flux which may thread the space between the two wires of a telephone line, or any varying electrostatic field about the line, will set up a varying current in the line, and if the frequency is such as to produce in the receiver a sound of audible pitch, this sound will interfere with the proper function of the receiver. Any noise produced in this manner by one telephone line on another is called "cross-talk." Noise may be produced in a similar manner by the induction from other sources, such as railway or lighting (alternating) circuits; see above.

To prevent such cross-talk or noise the wires of a telephone line are usually transposed every quarter of a mile. Fig. 1 shows a common transposition scheme. The vertical lines represent the cross arms of the poles where the

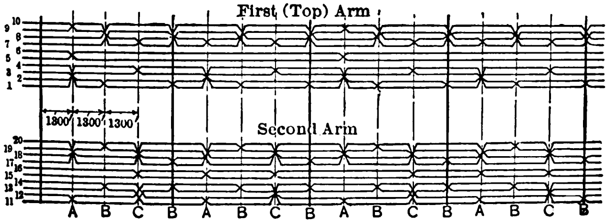

Fig. 1. Transposition Scheme

transpositions are made. The ordinary method of making a transposition is to cut each wire at each transposition point for that wire and to fasten the two ends either to separate insulators or to an insulator with two grooves, and then make the cross-overs with short wires. Transpositions can also be made without cutting the wire by using a single insulator with two grooves one well above the other. This scheme, known as the "single pin transposition," is also cheaper than the ordinary scheme.

The transpositions for the first and second cross arms are not alike, as shown in Fig. 1; when there are more than two cross arms, the wires on the odd numbered arms are usually transposed in the same manner as the first or upper arm, and the wires on the even numbered arms in the same manner as those on the second arm. When phantom circuits are used the wires on the several arms are not transposed alike.

Telephone Cables for either aerial or underground use are made as follows: Soft copper wires are insulated with dry paper laid on spirally; two such insulated wires then are twisted into a pair, the two wires having different colored papers; a number of pairs are laid up spirally to form a cylindrical core. The core then is wrapped spirally with paper tape, is dried thoroughly and a lead sheath molded on it in a lead press. Many users require three per cent of tin in the lead sheath.

The external diameter and weight of a cable containing a given number of pairs depend upon how closely the wires are wrapped together, and this in turn determines the capacity of the wires, the capacity being greater the closer the wires are wrapped together. Table III gives the dimensions and weights of standard cables.

Telephone cables, if used in connecting subscribers' telephones to central offices, usually are formed of 22 B. & S. gauge wires, except for long loops, when No. 19 B. & S. is generally used. For trunk lines between offices in large exchanges, cables are usually formed of No. 19 B. & S. gauge wires. Loading

TABLE III. PROPERTIES OF STRANDED TELEPHONE CABLES

No. pairs	Gage B. & S.	Electro-static capacity	Thickness of sheath, inches	Approximate external diameter, inches	Approximate weight per foot, pounds
5	22	High	1/12	0.48	0.55
10	22	High	1/12	0.59	0.71
15	22	High	1/12	0.66	0.83

43	13	Low	1/8	2.88	7.17
50	10	High	1/8	2.88	8.95

Note.—High capacity, 0.067–0.090 mutual, 0.10–0.12 grounded. Low capacity, 0.054–0.067 mutual, 0.080–0.10 grounded.

coils are used in trunk lines, and successful operation of the largest exchanges would be impossible without loading coils.

Cables for long distance purposes have large wires. Where conditions permit the use of loaded cables between cities, the operating conditions are most uniform. Chicago and New York are connected to cities within a radius of two hundred miles by loaded underground cables, and that practice is extending. The principal advantages are that the cables are not disturbed by storms and their insulation does not vary. The insulation resistance affects the attenuation and distortion of the waves sent over the wire. Lines equipped with loading coils are particularly sensitive to changes in insulation resistance. If the leakage in wet weather greatly exceeeds the normal leakage the loading coils may do more harm than good.

Installation of Cables. — (*See also Conduits and Conduit Lines, Underground; Wires and Cables.*) It is of particular importance in all operations connected with telephone cables to keep the core dry. The conductors are insulated only by paper, which is useless if moist and is of value only because it incloses dry air. As soon as the sheath is removed from a cable for splicing or terminating, the paper absorbs moisture from the air and from the hands; therefore expose the core as little as possible and boil out all moisture by pouring hot paraffine over and through the conductors before finally closing the cable.

Splicing. — To splice a telephone cable, a lead sleeve is slipped over one of the ends and the sheath cut off of each of the ends, after scraping bright the part at which the sleeve later is to be soldered with wiped joints. The core now is bound tight with dry muslin just at the end of the sheath and the muslin packed under slightly. The cable ends are boiled in hot paraffine by pouring or immersion. If white fumes arise from the paraffine it is too hot. The wires then are joined by stripping the paper from the ends, twisting the bared parts together so as to include a little of the insulation, then sliding down a paper sleeve previously placed over one wire.

When all the pairs are spliced, the conductors are again boiled out with paraffine. The lead sleeve is slipped into place, its ends dressed down and a wipe joint made at each end. This gives the splice a sheath continuous with the cable itself. A *Y-splice* is one in which one cable branches into two.

Cable Terminals are devices in which the paper insulated wires of a telephone cable are made accessible to wires outside the cable. The fundamental requirement is that the insulation of the conductors shall be maintained, both by keeping moisture from the cable insulation and by insulating the points to which the wires outside the cable attach.

A standard form of cable terminal consists of a box of porcelain, or partly iron and partly porcelain, wherein the end of the cable is sealed by bituminous compound. Binding posts in the porcelain receive the cable wires inside the sealed part and the outer wires on the outside.

Potheads are splices between rubber-insulated wires and paper-insulated cable wires. They are filled with bituminous sealing compound, so that moisture shall not lead to the paper insulation along the rubber-insulated wires.

Potheads are less widely used than before the development of the porcelain terminal. They are necessary for places where more than 50 pairs of wires are to be terminated. At the junction between aerial and underground cables, fuses require to be inserted to complete the protective system. Potheads then are placed on both cables, and the rubber covered wires led to the fuse terminals. It is good practice to house the fuses and pothead ends in wood or metal protecting boxes.

Drop Wires. — The wires used to connect open wire lines or aerial cables to subscribers' premises are called drop wires and are of hard drawn copper insulated with rubber, covered with a braid, then twisted into pairs. Standard sizes are No. 16 B. & S. gage in regions where ice does not form, and No. 14 B. & S. gage in other regions. No. 17 B. & S. copper-clad steel wire is successfully used as a substitute for either.

ELECTROLYSIS of the sheaths of underground telephone cables takes place when the sheaths carry stray direct current from one region to another if the current leaves the sheath in the presence of moisture (*see Electrolysis of Grounded Structures*).

COSTS. — The cost of building a telephone line depends on so many variables that no data of any value can be given in the space here available. Approximate costs of the various constituent items will be found in the articles on *Conduits and Conduit Lines, Cross Arms, Insulators, Poles for Overhead Lines, Wires and Cables, etc.*

BIBLIOGRAPHY. — See *Bibliography* in article on *Telephone Instruments and Circuits.*

[S. G. McMeen.]

TELEPHONE TRAFFIC AND RATES.— (*See also Telephone Instruments and Circuits; Telephone Lines.*) For the purpose of charges against telephone users, the unit of telephone traffic is the "conversation." For the purpose of designing and using telephone equipment the telephone "call" often is the unit. A call does not always result in a conversation. Telephone traffic is subject to general variations closely linked with variations in human activities. Obviously, telephone traffic relative to business is lower on holidays than on working days; on all days telephone traffic varies with the hours, in a way fairly uniform from day to day. It is possible to plot this variation, and Fig. 1 is a load curve representative of what happens each working day in most regular exchanges. The number of calls which subscribers originate depends on the kind of service rendered, whether residence, business, etc., and on the method of charging. Subscribers will call about twice as often under flat rates as under measured rates.

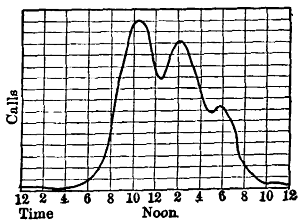

Fig. 1. Load Curve

A knowledge of the amount of traffic in a system, of its distribution as to time and as to divisions of the exchange, is important. By that knowledge the equipment must be designed, modified from time to time and the load distributed upon it as changing circumstances shall require.

Methods of Counting Calls. — Amounts of traffic are observed in three general ways. A peg-count is a record made by the operator actuating some counting device for each call answered or completed. A second way is to determine a ratio existing, for the particular time and place, between the calls in a given period and the average number of cord circuits in use in that period. Knowing these, the probable total can be computed from the cord circuit as counted. The third method is applicable to offices having service meters on all lines and is to associate one master meter per position with all the meters of that position, so that it will count one each time any service meter of the position is operated.

Operator's Speed. —The number of calls an operator can complete in an hour depends on the percentage of total calls which she must trunk to other offices. With standard manual equipment, for example, she can complete 240 calls in an hour if none have to be trunked, and 165 in an hour if 90 per cent of them have to be trunked.

Prompt disconnection is of great importance. A rule should be that disconnect signals shall be given prompt attention by some operator and shall take precedence over a call for connection. A flashing keyboard lamp indicating a recall should be given precedence over all other calls.

TRUNKING. — Traffic studies enable the determination of the number of trunks required for an anticipated traffic. The number of trunks required between two central offices, or between a central office and a private exchange, depends upon the number of calls which must be trunked per maximum or busy hour. The element of the probable coincidence in the time at which the calls will be made must be considered, and for this reason the more trunks installed the greater will be the number of calls which each trunk may be expected to handle. The following illustrate current practice:

Trunked calls per busy hour	35	90	1080
Number of trunks required	5	10	60
Calls per trunk	7	9	18

TELEPHONE RATES. — Rates for telephone service are of two kinds, "flat rates" and "measured service rates." Under flat rates, a fixed sum per month is charged and the subscriber may use his telephone as much as he pleases. Under measured service rates, the subscriber is charged a certain sum for each conversation he originates. Ordinarily also the subscriber guarantees to pay not less than a certain minimum amount per month. Rates for private exchanges often are made up by charging a rate per month for each local telephone, another rate per month for each section of local switchboard, another rate for each trunk line, and a still further rate for each outward call over the trunk lines leading from the private exchange, the monthly charge being the sum of all.

The cost of telephone service depends on the amount of use, though there is a fundamental cost of being prepared to furnish service. There is a tendency to change from the flat-rate to the measured-rate system. The latter is in operation in most large cities.

Flat-rate Systems. — In flat-rate systems there is no continuous effort to record the number of conversations. Counting is done from time to time for statistical purposes.

Measured-rate Systems. — In measured-rate systems it is necessary to record the conversations as they occur, so that each subscriber may be charged for the service he receives. Sometimes this is done by hand on tickets, but that method interferes with the operator's regular work, losing not only her service in operating but wasting switchboard investment by not using it efficiently. The best way is to equip each line with a meter under electrical control which causes it to count one unit for each completed conversation. Such meters are in extensive use in the larger cities. In manual systems, when a conversation takes place, the operator presses a meter key associated with the answering cord, and this makes the record upon the meter. In automatic systems the answering of the called station operates the meter.

In certain offices in London usual calls are charged at a penny each and certain special calls at two-pence each. In trunking calls of the latter kind, the operator is reminded of the higher charge by the lighting of a specially colored lamp as she uses the trunk order key. Being so reminded, she presses the meter key twice when such a conversation occurs, the result being that the calling subscriber pays two-pence for each such special call, because his meter records two units for each.

LONG-DISTANCE CALLS are those which occur between cities, as distinct from those within cities, no matter how large the latter may be. Long-distance calls usually are handled by special operators at special switchboards connected by trunks to the switchboards which handle city service. Long-distance calls usually require that a particular person be found in the called city, and the record of such calls includes the name as well as the number of the called person. On this ticket is recorded the duration of the conversation in minutes and fractions so that the charge may be computed. This elapsed time is best recorded by a time-computing machine which prints a record.

Two-number Method. — Where calls between cities reach a sufficient number, it is found economical to provide for connecting by number only the stations of the subscribers who call frequently, and this is called the "two-number" method. Such connections generally are established without trunking to and from special long-distance switchboards. Operators at regular multiple-switchboard positions make and complete these calls. They are ticketed only at the originating end.

COIN-COLLECTING DEVICES. — Measured service calls, either local or long distance, may be made over telephones equipped with coin-collecting

devices. These are so arranged that the operator making the connection knows in advance of conversation that the proper amount of money has been placed in the machine. Machines of one type require the deposit of the coin before the central office can be signaled at all; the coin is returned if the call is not completed. Machines of the other type require that the coins be deposited after the order has been given but before the conversation occurs.

DEVELOPMENT STUDIES — FACTORS AFFECTING COSTS. — A development study is an inquiry to determine what kind and what amount of construction or reconstruction is warranted by the conditions and probabilities of a region. Some form of development study always precedes such work. Economical construction and efficient operation require constant improvement in development-study methods and their use.

Forecasting Requirements. — In cities a first step is to forecast the future development through a period of from 15 to 20 years. This is done by examining statistics of growth. Ratios of telephones to population then are tabulated for the past, and future ratios estimated. A house count then is undertaken. This means the counting of existing buildings and the estimating of the telephone-using abilities of the occupants. At the same time a forecast is made of the probable future development of each region as it is studied.

Determination of Number of Central Offices. — If the exchange will require switchboards for more than 10,000 lines there will be more than one central office. The more switchboards there are in a town, other things being equal, the shorter will be the average length of subscribers' lines, and the greater will be the mileage of trunk lines. The more offices there are, the greater the cost of owning and maintaining the buildings for them, and the greater the cost of operating the equipment in them. A balance for these conditions must be found.

The economical number of districts having been determined, the office of each district can be located so as to attain the greatest wire economy. The conduit runs and pole lines then are laid out for the subscribers' and trunk lines. Speaking generally, it is good practice to provide a main conduit passing the central office and having cross routes extending from it at right angles, one on each alternate street or in alleys if they exist.

In automatic practice, it is possible further to subdivide exchange districts and to place some of the apparatus in small sub-district offices having trunks leading to the district office, still other trunks interconnecting all the district offices. This lowers still further the cost of subscribers' lines and increases still further the cost of trunk lines.

[S. G. McMeen.]

TELPHERAGE. — (*See also Conveyors.*) Telpherage is a name given to a system of transporting materials in which the load is suspended from a trolley or small truck running on a cable or overhead rail, and in which the propelling force is obtained from an electric motor carried on the trolley. The trolley, with its motor, is called a "telpher." A historical and illustrated description of the system is given in a paper by C. M. Clark, in *Trans. A.I.E.E.*, 1902. See also circulars of United Telpherage Co., N. Y.

[Wm. Kent.]

TEMPERATURE AND THERMOMETERS. — (*See also Heat and Thermal Properties; Pyrometers; Thermodynamics, Principles of; Units and Conversion Factors.*) The temperature of a body may be defined as its relative hotness or coolness referred to some standard substance under standard conditions. The change in some physical property of a standard substance must be utilized in order to give a number to temperature. Any device which serves this purpose is called a thermometer; if the device is applicable to the measurement of very high temperatures it is also called a pyrometer, q.v.

TEMPERATURE SCALES. — The standard* temperature-measuring device is the constant volume hydrogen thermometer, which consists essentially of a suitable receptacle containing a constant mass of hydrogen gas kept at constant volume, viz., the volume it would have at a pressure of 1000 millimeters of mercury and at the temperature of melting ice, with means provided for measuring any variation that may be caused to take place in the pressure of the gas.

Centigrade Scale. — The temperature of melting ice at a pressure of 760 millimeters of mercury is arbitrarily taken as zero degrees, and the temperature of saturated steam at a pressure of 760 millimeters of mercury is taken as 100 degrees. Calling p_0 the pressure of a constant volume of hydrogen gas when the receptacle is immersed in the melting ice and p_{100} its pressure when immersed in the saturated steam, and p_t its pressure when immersed in any given substance (the pressure in each case being measured after the lapse of a sufficient time for it to reach a constant value), the numerical value of the temperature of the given substance is defined as

$$t = \frac{p_t - p_0}{p_{100} - p_0} \times 100.$$

A degree centigrade is abbreviated deg. cent. or °C.

Fahrenheit Scale. — The Fahrenheit scale of temperature is derived in the same manner, except that the temperature of the melting ice is taken as 32° and the boiling point of water (at 760 millimeters mercury) as 212°. A temperature of t_f degrees Fahrenheit is then equal to

$$t_c = \tfrac{5}{9}(t_f - 32) \qquad \text{degrees centigrade.}$$

Vice versa, a temperature of t_c degrees centigrade is equal to

$$t_f = \tfrac{9}{5}t_c + 32 \qquad \text{degrees Fahrenheit.}$$

A degree Fahrenheit is abbreviated deg. fahr. or °F.

Réaumur Scale. — This scale, which is used to some extent in Europe and in breweries in this country, is defined in the same manner as the centigrade scale, except that the boiling point of water (at 760 millimeters mercury) is taken as 80°. A temperature of t_r degrees Réaumur is then equal to

$$t_c = 1.25\, t_r \qquad \text{degrees centigrade.}$$

Platinum Scale. — See article on *Pyrometers.*

ABSOLUTE TEMPERATURE. — Let p_0 = absolute pressure of a given mass of gas at 0° C., p = absolute pressure of this same mass of gas at any temperature t° C. as above defined. For all values of t between about −150° and +1000° C., i.e., for all values of t within the experimental range, it is found

* Adopted by the Bureau International des Poeds et Mesures.

Example: − 12° C.= 10.4° F.; − 33° C.= − 27.4° F.; 13° C.= 55.4° F.

that, in the case of the so-called permanent gases (i.e., those which are not readily liquefied, such as air, hydrogen and nitrogen), the following relation exists between p_0, p and t provided there is no change in volume

$$p = p_0 (K + t),$$

where K is a constant, approximately equal to 273 to within less than 1 part in 300.* Consequently, assuming this relation to hold when the pressure p becomes zero, the value of t which would correspond to *zero* absolute pressure is

$$t_0 = -273° \text{ C.}$$

This temperature is called the absolute zero. That is, the zero of the centigrade scale is 273° C. above the absolute zero.* Similarly, the zero of the Fahrenheit scale is approximately 460° F. above the absolute zero.

* For hydrogen Callender gives the value 273.10.

The temperature measured above the absolute zero is called the absolute temperature. Let t_c = temperature in ° C. above the centigrade zero, t_f = temperature in ° F. above the Fahrenheit zero, then the absolute temperature in ° C. corresponding to t_c is

$$T_c = 273 + t_c,$$

and the absolute temperature in ° F. corresponding to t_f is

$$T_f = 460 + t_f.$$

Absolute Thermodynamic Temperature. — (*See article on Thermodynamics, Principles of.*) The difference between the temperature scale as defined by the constant-volume hydrogen thermometer and the absolute thermodynamic scale is less than 0.1° C. at ordinary temperatures, and is less than 1° C. throughout the range from − 150° to 1000° C.

THERMOMETERS. — The standard constant-volume hydrogen thermometer is seldom used except for standardizing purposes, and then only for temperatures up to about 500° C. The constant-volume nitrogen thermometer is used for standardizing purposes for temperatures up to about 1500°. For higher temperatures radiation pyrometers are used as standards (*see Pyrometers*).

Mercury-in-Glass Thermometers. — For ordinary temperature measurements, between about − 35° C. and 350° C., the ordinary mercury-in-glass thermometer is almost universally employed. The temperature may be read directly from the position of the end of the mercury column as given by a uniformly divided scale on the stem, provided the 0° and 100° points have been properly located and the stem has a uniform bore.

For accurate measurements the scale on the thermometer should be checked to determine whether the 0° and 100° points are properly located and whether the bore is uniform. Unless the proper quality of glass is used the bulb does not return to exactly the same volume after successive heatings. Even when a high-grade thermometer is employed, the zero should be frequently checked if the thermometer is used for high-temperature measurements.

Methods of calibrating mercury thermometers are described in text books on heat, but at the present day it is more convenient to compare the thermometer with a secondary standard mercury thermometer which has been calibrated by a central standardizing bureau, such as the Bureau of Standards at Washington.

High-range Mercury Thermometers. — The mercury thermometer when made of very hard glass and filled under pressure with the space above the mercury column containing some inert gas, like nitrogen, may be used to measure temperatures up to about 550° C. If a considerable length of stem emerges into the air, a very considerable error, 25° C. or so, may be introduced at high temperatures. This "stem correction" varies slightly with the kind of glass but may be represented very nearly by the formula

$$\text{Correction to be added to reading} = 0.00016\, n(t_b - t),$$

where the temperatures are all in degrees centigrade and n = number of degrees emergent from bath or furnace, t_b = temperature of bath and t = mean temperature of emergent mercury column.

COSTS. — Ordinary mercury thermometers cost from 50 cents to $5.00 apiece, depending upon the accuracy of their calibration. A 100° C. mercury thermometer sufficiently accurate (error not over ½ per cent) for ordinary engineering work costs about $4.00. A 400° C. mercury thermometer costs about $6.00 and a 550° C. mercury thermometer about $12.00.

[H. PENDER and H. R. RANKEN.]

THERMODYNAMICS, PRINCIPLES OF. — (*See also Electrochemistry, Principles of; Heat and Thermal Properties; Steam; Steam Engines; Temperature and Thermometers.*) "Thermodynamics" is a general name employed to include all problems involving the transfer of energy from one body to another, and the transformations of energy within a body. The word "energetics" is a better general term to designate such problems, but the term "thermodynamics" is the one ordinarily employed, since heat (Greek, "thermos") is developed in practically every case of transfer or transformation of energy. The transfer of energy from one body to another in every known instance is found to be consistent with the following fundamental principles or laws:

FIRST PRINCIPLE OF THERMODYNAMICS. — All known experimental facts are in accord with the principle that, when a body changes from a given state or condition 1 to any other given state or condition 2, the total energy given out by the body is always the same, independent of how the change takes place.

Intrinsic Energy. — Any given body in any given state or condition may, therefore, be considered as having associated with it a definite amount of energy, which, in general, changes when the state or condition of the body changes. This energy is called the "intrinsic energy" of the body, and depends solely upon the state or condition of the body. If the intrinsic energy in a given state or condition 1 is U_1, and in some other state or condition 2 is U_2, then the total energy given out by the body when it changes from the state 1 to the state 2 is $U_1 - U_2$, and this difference depends only upon the initial and final states of the system and is independent of how the body passes from one state to the other.

Heat and Work. — The energy given out by a body may be either heat, mechanical work, electrical, magnetic or other forms of energy. For convenience, all other forms of energy given out by the body than heat, may be called the "external work" done by the body. Hence, calling Q_e the heat *evolved* and, W the external work *done by* a body when it changes from a state 1 to a state 2, the total energy given out by the body may be expressed as $Q_e + W$. In general the amount of heat evolved and the external work done by a body when it changes from a state 1 to a state 2 depend respectively upon the manner in which the change takes place, but the sum of the heat evolved and the work done is always the same for given initial and final states, irrespective of how the change takes place.

Mathematical Expression of First Law. — Equating the two expressions given above for the total energy transferred from a body when it changes from a state 1 to a state 2, gives the relation

$$U_1 - U_2 = Q_e + W,$$

which is the usual mathematical expression of the first law of thermodynamics. If, in the change from state 1 to state 2, heat is actually evolved, then Q_e is positive, while if the heat is absorbed Q_e is negative. It is usually more convenient to consider the heat absorbed by the body as a positive quantity. Hence, putting $Q = -Q_e$ the above expression may be written

$$W = U_1 - U_2 + Q, \tag{1}$$

in which U_1 is the intrinsic energy of the body in any state 1, U_2 the intrinsic energy in any other state 2, Q is the heat *absorbed* and W is the *work done by* the body when it changes from the state 1 to the state 2.

PATH OF CHANGE. — Consider a body which changes from a state or condition 1 to another state or condition 2. In changing from the initial

state to the final state the body passes through a series of successive states, each state differing but infinitesimally from the preceding. The given series of states through which the body passes is called the "path" from state 1 to state 2. In general, a body may pass from a state 1 to a state 2 by an infinite number of such paths; therefore, a change can be completely specified only by stating the "path" of the change as well as the initial and final states.

The *sum* of the work done and the heat given by a body when it changes from a state 1 to a state 2 depends only upon these states, i.e., upon the ends of the path, but the proportions of the energy given out as work and heat respectively depend not only upon the series of successive states through which the body passes (i.e., the "shape" of the path), but also upon the relation of the given body to any external bodies which may in any way affect it.

ADIABATIC PROCESS.—Any process by which a change can be produced in a body under conditions such that the body neither absorbs nor gives out heat to any other body is called an "adiabatic" process. Adiabatic processes can never be completely realized, since no known substance is a perfect heat insulator, but such processes can be closely approximated, e.g., the expansion or compression of a gas in a cylinder with well-insulated walls when the expansion or compression is so rapid that no heat is conducted through the walls.

ISOTHERMAL PROCESS.—Any process by which a change can be produced in a body without changing its temperature is called an "isothermal" process. For example, the melting of ice, when the ice and water are kept well stirred, is an isothermal process.

REVERSIBLE PROCESS.—Whenever a change takes place in a body A, a change also takes place in some other body or bodies B. If the changes in the system formed by A and B are such that the path of each change may be reversed in direction without changing by an appreciable amount the total energy of the system, then the process by which the change takes place is called a "reversible" process.

Since heat can pass only from a hot to a cold body and never in the reverse direction (definition of heat), it follows that, if during any step of a process there is a transfer of heat between bodies whose temperatures differ by a finite amount, then the process is irreversible. Hence, a reversible process can take place under two conditions only: either there must be no transfer of heat (adiabatic process) or the transfer of heat must be between bodies which differ in temperature only by an infinitesimal amount.

Strictly speaking, the last type of process is absolutely reversible only in the limiting case when the bodies between which the transfer of heat takes place are at exactly the same temperature. This condition can be only approximated since there must always be a difference in temperature, though this difference may be infinitely small, in order that a transfer of heat may take place.

SECOND LAW OF THERMODYNAMICS.—The so-called second law of thermodynamics involves three distinct principles, which may be stated as follows:

1. When a body changes from a state 1 to a state 2 by any *reversible* process, and then back from 2 to 1 over the same path, but in the reverse order, then the heat absorbed by the body during the change from 1 to 2 is exactly equal to the heat evolved by this body during the reverse change from 2 to 1.

2. When a body changes from a state 1 to a state 2 by any irreversible process, the heat *absorbed* during this change can never be greater than the heat which it would absorb were the change from 1 to 2 over the same path produced under conditions which would render the process reversible. Similarly, if the body gives out heat during an irreversible change, the heat given out can never be

less than the heat which it would give out were the change over the same path produced under conditions which would render the process reversible.

3. The heat (Q) absorbed by a body during any reversible isothermal process bears the following relation to the temperature (t) of the body during the process,

$$Q = MK\,(t + T_0), \tag{2}$$

where M is the mass of the body, T_0 is a constant which depends *solely upon the scale on which the temperature is measured*, and K is a constant which depends *solely upon the nature of the body and its initial and final states.*

Absolute Thermodynamic Temperature. — It is found impossible by any known means to produce a negative temperature, as measured on any temperature scale, numerically greater than the corresponding value of constant T_0 in the above expression (equation (2)). Hence that temperature below the zero of any given scale equal to this constant T_0 is called the "absolute thermodynamic zero" of this scale, and the temperatures measured from this point are called "absolute thermodynamic temperatures." Equation (2) may therefore be written

$$Q = MKT, \tag{2a}$$

where $T = (t + T_0)$ is the absolute temperature corresponding to the temperature t. The value of the absolute thermodynamic zero is practically the same as that temperature, as measured on the constant-volume hydrogen-gas thermometer, at which the pressure of the gas would be zero, assuming the decrease in pressure per degree ($= 1/273$ of the pressure at 0° C.) to remain constant at all temperatures.

On the centigrade scale the absolute zero is, therefore, $-273°$ (approximately), and on the Fahrenheit scale $-460°$ (approximately).

Entropy. — Since the factor K, in equation (2) above, depends solely upon the nature of the body and its initial and final state, this factor may be looked upon as representing a change in a property of the body. That is, calling this property of the body for the initial state N_1 and for the final state N_2, then K may be put equal to $N_2 - N_1$, and equation (2) may be written

$$Q = M\,(N_2 - N_1)\,T. \tag{2b}$$

This equation, which represents the relation between the heat absorbed and the temperature, for a reversible isothermal process, may also be applied to an adiabatic process, if the property of the body represented by the symbol N is assumed to remain unchanged during such a process. For an adiabatic process the heat absorbed is zero, by definition, and this, on the assumption of no change in N during such a process, is consistent with equation (2b).

In general, the temperature of a body during any process is not constant, but the process may be considered as made up of a series of reversible isothermal and adiabatic steps, and the above definition of the property N may be applied to each step. That is, the change in N for each step composed of a reversible isothermal "tread" and an adiabatic "rise" is

$$dN = \frac{dQ}{MT},$$

where M is the mass of the body, dQ is the heat absorbed, and T is the absolute temperature of the body during this step.

This property N, whose increase during any step in a reversible process is equal to the heat absorbed per unit mass divided by the absolute temperature of the body during this step, is called the "entropy" of the body per unit mass. Since entropy is defined in terms of its change, its absolute value for any given

standard state of a body may be arbitrarily taken as zero. In steam tables, the entropy of water at 32° F. and at atmospheric pressure is usually taken as zero. The entropy of a body can in many cases be calculated from the other properties of the body. (*See article on Steam.*)

In accordance with the above definition of entropy the heat absorbed by a body when it changes from a state 1 to a state 2 by any *reversible* process is then

$$Q = M \int_1^2 TdN, \tag{3}$$

where M is the mass of the body, T its absolute temperature during any step of the process, and dN the increase in its entropy per unit mass during this step.

Principle of the Increase of Entropy. — It can be shown, from the principles above stated, that the only possible changes which can take place in a system of bodies to which no energy is added or subtracted are changes which involve an *increase* in the total entropy of the system. Reversible changes may theoretically take place without increasing the total entropy, but reversible changes never take place in nature nor can they be realized *absolutely* by any known experimental means.

MAXIMUM WORK. — The maximum external work which a body can do when it changes from a state 1 to a state 2 along a given path (i.e., by passing through a given series of states) is equal to the decrease in its intrinsic energy plus the maximum amount of heat it can absorb when it changes along this path. The maximum external work which a body can do in changing from a state 1 to a state 2 along a given path is therefore

$$W_{\max} = U_1 - U_2 + M \int_1^2 TdN. \tag{4}$$

The value of the last term in this expression depends upon the temperature at each step in the change, and this temperature depends upon the "path" along which the change takes place. If the path is such that *all* the heat is absorbed at one given temperature T, then

$$W_{\max} = U_1 - U_2 - TM(N_1 - N_2). \tag{4a}$$

This may also be written

$$W_{\max} = U_1 - U_2 + T\frac{dW_{\max}}{dT}, \tag{5}$$

where $\frac{dW_{\max}}{dT}$ is the rate of increase of the maximum work done by the body with the temperature at which the heat is absorbed.

Free Energy. — The maximum work which a body can do in changing from a state 1 to a state 2 is sometimes referred to as the "free energy" of the body corresponding to this change. This free energy depends not only upon the initial and final states of the body itself but also upon the temperature of the hottest external body available as a source of heat; this is apparent from equation (4).

CYCLIC PROCESSES. — In the theory of the steam and other heat engines the question arises as to what is the maximum amount of external work which can be obtained from a body by alternately heating it to a high temperature and then letting it do work (e.g., by expanding), thereby cooling to a lower temperature, this cycle of operations being repeated over and over again. That is, the body or "working substance" changes from a state 1 to a state 2, then back again to 1, then changes again to 2, and so on for any number of cycles. The intrinsic energy of the body at the beginning and end of any cycle is then the same, and therefore, the net work done by the body during any cycle is

the difference between the heat actually absorbed and that actually given out during the cycle.

Thermal Efficiency.—The ratio of the net work done to the heat absorbed during the cycle gives the proportion of the heat added which is converted into external work, and is called the "thermal efficiency" of the cycle.

Carnot's Cycle.—From the principles stated above it follows that the heat absorbed will be a maximum when this heat is absorbed in a reversible manner under conditions such that the temperature of the working substance is the same as that of the hottest body available as a source of heat; and the heat given out is a minimum when this heat is given out in a reversible manner under conditions such that the temperature of the working substance is the same as that of the coldest body available as an absorber of heat. The "path" along which the body changes (*see* Fig. 1) will then consist of an isothermal change at temperature T_1, an adiabatic change to a lower temperature T_2, an isothermal change at this temperature T_2, and then a second adiabatic change to T_1. Such a path is called a "Carnot's cycle." The figure represents such a path for a perfect gas, the ordinates being pressure and volume.

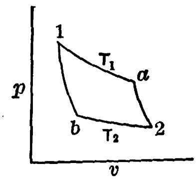

Fig. 1.

From the general expression for maximum work, equation (4), it follows that the efficiency of this cycle is

$$\frac{W}{Q_1} = \frac{T_1 - T_2}{T_1}.$$

For a given amount of heat added to a working substance, during a cyclic change, the maximum possible work which the working substance can do is that done when the cycle is a Carnot's cycle, and this maximum work is directly proportional to the difference between the temperature of the body from which the working substance absorbs heat and the temperature of the body to which it gives out heat, and is inversely proportional to the absolute temperature of the body from which it absorbs heat.

APPLICATIONS OF THE LAWS OF THERMODYNAMICS.—The laws of thermodynamics serve as the basis for the mathematical treatment of the performance of the steam engine, steam turbine, internal-combustion engines, refrigerating machines, air compressors, etc.; they are also involved in many important electrochemical relations (*see Electrochemistry, Principles of*). It is beyond the scope of this book to go into these matters here; see the treatises listed in the following bibliography.

[H. PENDER.]

THIRD-RAIL, OR CONTACT-RAIL, SYSTEMS. — (*See also Bonds and Bonding; Rails, Track and Third; Standardization Rules of the A.I.E.E.; Trolley Systems, Overhead; Trolley Systems, Underground.*) The following is a brief table of contents of this article:

The contact rail, or third rail, is a conductor supported on insulators near the ground and presenting a continuous contact surface to a collector or shoe attached to the rolling stock. In its commonest form it is a rail of standard section supported at intervals of a few feet by substantial insulators, electrical continuity between adjacent lengths being obtained by copper bonds across the joints.

TERMINOLOGY. — The following terms and definitions are used in connection with third-rail systems.

Contact Shoe. — A third-rail contact shoe is a conductor, fastened to the rolling stock, which is designed to make electrical contact with the third rail. This is hereinafter referred to as the "shoe."

Contact Surface. — The contact surface of a third rail is the surface against which the shoe presses.

Gage of Track. — The minimum clearance between the inside surfaces of the heads of the two track rails, i.e., the distance *A* in Fig. 17. The track gage in this country is 4 feet 8½ inches.

Third-rail Gage. — The distance measured parallel to the plane of the top of both running rails, between the gage line of running rails and the gage line of third rail, i.e., the distance *B* in Fig. 17 of this article. (The Am. Elect. Ry. Assn. 1912.)

Location. — Third-rail locations will be described in terms of the third-rail gage and the vertical distance (*C* in Fig. 17) between the normal contact surface and the normal top of the track rail. See also Table II below.

Top-contact Rail. — A top-contact third rail is one on which the contact surface is on the upper side of the rail.

Under-contact Rail. — An under-contact third rail is one on which the contact surface is on the under side of the rail.

Third-rail Insulator. — A third-rail insulator is that portion of the third-rail support which forms the principal electrical insulation.

Insulator Base or Bracket. — A third-rail insulator base or bracket is a device used to support the third-rail insulator.

Incline. — An incline is a portion of third rail sloped to gradually bring the shoe from its free position into contact with the normal surface of the third rail.

End Incline. — An end incline is an incline at the end of a run of third rail and is made to receive shoes moving in line with the third rail.

Offset-end Incline. — An offset-end incline is an incline *at the end* of a run of third rail and is made to receive shoes moving laterally towards the third rail.

Cross Incline. — A cross incline is a combination in one piece of two end inclines from adjacent third rails which meet at a turn-out.

Side Incline. — A side incline is an incline at *the side of* a third rail and is made to receive shoes moving laterally towards the third rail.

Offset-side Incline. — An offset-side incline is an incline offset from the standard third rail in order to gain clearance between the third rail and the maximum equipment line of the rolling stock.

Maximum Equipment Line. — The maximum equipment line is the boundary which encloses the cross-sectional outlines of all the rolling stock, under all operating conditions.

Third-rail Protection. — A third-rail protection is a partial covering of the third rail which affords some degree of protection from the weather or from accidental contact with foreign bodies.

Third-rail Anchorage. — A third-rail anchorage is a device to prevent the third-rail creeping longitudinally.

Tie Motion. — Unless otherwise specified, tie motion will be understood to mean the vertical play of the ties caused by the passage of trains.

TYPES OF CONSTRUCTION. — Third-rail construction may be classified into the top-contact and under-contact types, each of which is susceptible of important variations in design, especially with reference to the type of protection.

Interborough Top-contact Type (Fig. 1). — One of the most commonly used types is illustrated in Fig. 1. It is often called the "Interborough Type" on account of its use in the subways of the Interborough Rapid Transit Co., of New York. The rail is a standard T-section and rests on reconstructed granite insulators. A board protection is attached to the rail itself by means of clamps and uprights and is thereby kept in perfect alignment.

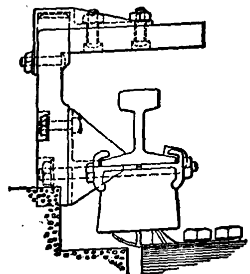

Fig. 1. Interborough Top-contact Type

Pennsylvania Top-contact Type (Fig. 2). — Another type has the protection supported on separate brackets independent of the third rail itself. It is claimed that this reduces the amount of labor which has to be done on the live rail, when repairs are being made, but it cannot be relied upon as well as the Interborough type to keep the rail and protection in perfect alignment.

London Tube Type (Fig. 3). — The mounting and location of the third rail and the negative contact rail of the London Tube Railways is illustrated in Fig. 3.

Under-contact Types (Figs. 4, 5, 6 and 7). — While the top-contact types have given first-class service, they are considered to have certain disadvantages for exposed locations as they cannot be wholly protected from snow, ice and sleet. The lower part is only a few inches from the ties, while holding clips generally reduce this clearance, increasing the danger of grounding from accumulation of wet snow and ashes and from flooding. The occasional suspension of traffic during sleet and snowstorms and floods, on railroads using the top-contact type of third rail, led to the idea of an under-contact third rail loosely clasped

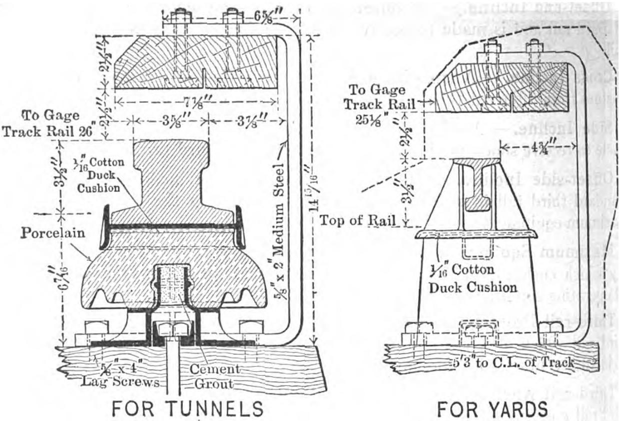

Fig. 2. Pennsylvania Top-contact Type

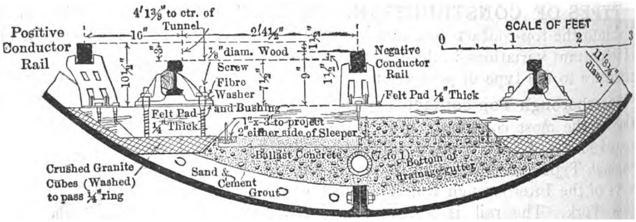

Fig. 3. London Tube Type

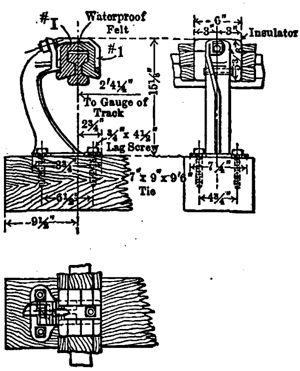

Fig. 4. Type X Bracket, for use on Straight Work

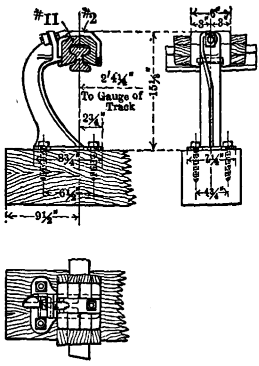

Fig. 5. Type Y Bracket, Applied to End Incline

in insulators by hook bolts hung from brackets, with the top and sides of the rail completely sheathed in a flexible insulating material for protecting the rail from accidental contact with man and beast, and from sleet, snow and spray. With this type of rail (Figs. 4, 5, 6 and 7) the protection is of such character that there is no packing of snow between the sheathing and the contact rail, as in

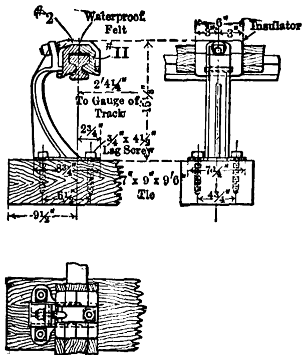

Fig. 6. Type Z Bracket, for use with end inclines A at frogs

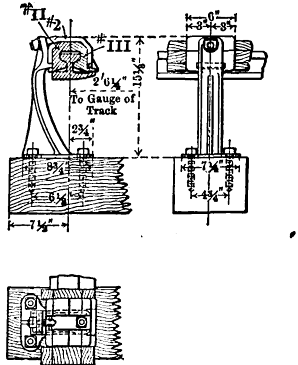

Fig. 7. Type W Bracket, for use with offset end inclines B at frogs

some other forms, and in sleet storms no ice forms on the contact surface; some icicles may form at the edge of the petticoats, but hanging down clear of the edge of the rail, are easily broken off by the passing shoe. A special design, using a standard T-rail, is shown in Fig. 8, and is used for 1200 volts.

Where the rail is buried in snow, the passage of the contact shoe breaks the snow away, leaving the rail surface clear, instead of ironing the snow down on the rail, as may happen with the top-contact type.

Sheathing and Special Work. — The sheathing between the insulator blocks, depending upon local conditions and the price of materials, as well as the potential used, is usually formed of three wooden strips, one grooved on the under side and inclosing the head of the rail, and the other two, attached to and dependent from it, reaching in toward the web of the rail. Where good wood is not available, an alternative protection costing about the same and having a higher electrical resistance, although not so good mechanically, is a semi-flexible shell of indurated fiber conformed to the rail sections.

The special work, i.e., inclines, jumpers, etc., used with the under-contact rail, is shown in Fig. 9,

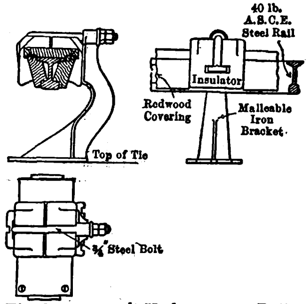

Fig. 8. 1200-volt Under-contact Rail.

Combined Top- and Under-contact Shoes. — The employment of collecting shoes on rolling stock so constructed as to press upwards on the under-contact rail and downwards on the top-contact type solves the question of interchange between railroads not using the same type.

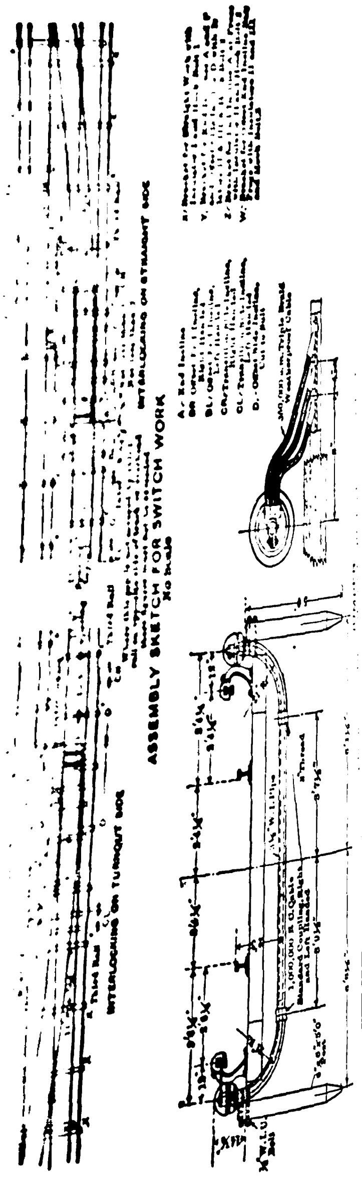
Third-rail Systems



CONTACT RAILS VERSUS OVERHEAD TROLLEY. — The contact rail is used as a part of the positive conductor system whenever the current to be collected by each collector exceeds the amount which can be taken safely from a trolley wire, or whenever the total current taken by a train exceeds the amount that can economically be carried by conductors of such expensive metal as copper or aluminum.

Positive Contact Rails. — Considered as a part of the positive conductor system, the contact rail and overhead trolley possess the relative qualifications given in Table I.

TABLE I. — RELATIVE QUALIFICATIONS OF THIRD RAIL AND OVERHEAD TROLLEY SYSTEMS.

(*Adapted from Table by C. E. Eveleth.*)

I Protected third rail	II Overhead high-tension bridge, catenary construction	III Overhead side bracket, catenary construction
Interference with track maintenance.	Entirely clear of road bed.	Same as II.
Can be maintained by section gang.	Requires special tools, crews and work trains.	Same as II, but not as important.
Easily cleared up and insulated when derailment occurs.	In the way of boom of derrick car — liable to be knocked down and put all tracks out of service.	Same as II.
Hindrance to coupling freights, etc. With protected rail this is not very serious.	Dangerous to freight brakemen on account of parts hanging down and small bridge clearance. Very difficult to install satisfactory ticklers to warn trainmen when approaching bridges.	This point is of less importance.
Interference with clearing snow between tracks.	Not affected.	Not affected.
Ease of satisfactorily collecting current on account of location, where relative motion between track and rail is small. Collectors may be safely replaced on the road.	Difficult to collect current, as a more complicated mechanism is required on account of the grade of the wire due to low clearances at bridges and high clearances at road crossings.	Similar to II.
May be readily inspected by track walker.	Requires a man with special training.	Similar to II, but of less importance.
Ease of sectionalization. Jumpers may be disconnected at the nearest adjacent road crossings.	Difficult of sectionalization.	Sectionalization not of so much importance.

TABLE I. — RELATIVE QUALIFICATIONS OF THIRD-RAIL AND OVERHEAD TROLLEY SYSTEMS — *Continued*

(*Adapted from Table by C. E. Eveleth.*)

I **Protected third rail**	II **Overhead high-tension bridge, catenary construction**	III **Overhead side bracket, catenary construction**
May be worked on while alive to make track changes or repairs, making system very flexible.	Requires that current be shut off no matter how slight repairs are, making system inflexible.	Similar to II, but not of such importance.
No interference with visual signals.	Signals located and seen with difficulty, as they must be lower than the bridges and even then have the distant bridges as a background. Dangerous to maintain signals in this location, as it must be done from ladders.	Not affected.
Danger of wreck from burning off track rail due to arcing current. This is a possible contingency, but one not very likely to occur.	Danger from dangling overhead work when messenger cable is burned off at a defective insulator.	Same as II.
Little interference with fire-extinguishing apparatus in the car storage yard.	Difficulty in removing cars on account of high-tension wires interfering with firemen.	Will probably have low-tension wires for this type of construction.
Absolute freedom from lightning disturbances.	Very much exposed to lightning.	Same as II.
Entire freedom from telephone and telegraph disturbances, also inductive effects on signal wires.	Difficult problem in connection with these interferences, affecting not only the railroad company's wires, but those belonging to other interests.	Same as II.
No trouble at grade crossings with crossing trolley wires.	Probably trolley crossings will have to be avoided by overhead or undergrade crossings.	Troubles similar to II.
Can add sidings or more tracks with little difficulty.	Can make such additions only at considerable expense.	Difficulty not very great.

TABLE I — RELATIVE QUALIFICATIONS OF THIRD-RAIL [illegible] OVERHEAD TROLLEY SYSTEMS—*Continued*

(*Adapted from Table by C. E. Eveleth.*)

I Protected third rail	II Overhead high-tension bridge, catenary construction	III Overhead [illegible] bracket [illegible] construction
[illegible] be worked on while [illegible] track [illegible] making [illegible] very [illegible]	Requires that current be shut off no matter how slight repairs are, making system inflexible.	Similar [illegible] tance.
[illegible] interference with visual signals.	Signals located and seen with [illegible], as they must be [illegible] the bridges and even then have the distant bridges as a background. Danger as to maintain signals in this location, as it must be done from ladders.	Not affected
[illegible] wreck [illegible] rail due to [illegible] current. [illegible] very likely to [illegible]	Danger from dangling overhead work when messenger cable is burned off at a defective insulator.	Same as II.
[illegible] interference with fire-[illegible]	Difficulty in removing cars on account of high-tension wires interfering with firemen.	Will probably [illegible] for this [illegible] construction
[illegible] from lightning [illegible]	Very much exposed to lightning.	Same as II.
[illegible] from telephone and telegraph disturbances, also [illegible] signal wires.	Difficult problem in connection with these interferences, affecting not only the railroad company's wires, but those belonging to other interests.	Same as II.
[illegible] at grade crossings [illegible] trolley wires.	Probably trolley crossings will have to be avoided by overhead or undergrade crossings.	Troubles similar to II.
[illegible] or more [illegible] with little diffi-[illegible]	Can make such additions only at considerable expense.	Difficulty not great.

Negative Contact Rails. — Negative contact rails are used as part of the negative-feeder system when the drop of potential in the track rails is limited to such a small amount that it is cheaper to use an insulated rail than to reinforce the track rails with feeders. Considered as part of the negative feeder system, the contact rail possesses the following advantages over the track-rail return system. If used in connection with a positive contact rail, the negative rail is placed between the track rails.

(I) When properly insulated, it eliminates every possibility of electrolysis.

(II) It gives the block-signal system complete independence from the electric-traction system. Among the advantages which this entails are, no unbalancing of signal circuits, saving the cost of reactance bonds (*see Signaling, Railway*) and increased economy in signal circuits.

(III) It gives greater safety to passengers.

(IV) It reduces the probability of short circuits.

(V) It decreases the cost of track-rail maintenance by the elimination of bonds.

(VI) It halves the first cost of bonds, as one high-conductivity contact rail usually replaces two track rails.

(VII) It reduces the wear of bonds by saving them from the shock of trains.

These advantages are usually offset by the first cost of the negative contact-rail, by the complications it introduces at special track work, and by the impossibility of protecting a central rail from snow and ice on account of insufficient clearance for any kind of covering.

ELECTRICAL DESIGN. — The calculations of potential drop, network, resistance, etc., are treated under *Trolley Systems, Overhead*. The composition, weight, dimensions, resistance and reactance of rails will be found in the article on *Rails, Track and Third*.

Selection of Suitable Rail. — When the various types of rail are under consideration it is well to arrange a table with the following headings, in order to compare the relative economy of the different types. (1) Circular mils of copper equivalent to rail; (2) Additional circular mils of copper required to equal the rail of highest conductivity; (3) Cost of rail for the entire railroad; (4) Cost of additional copper for entire railroad; (5) Total cost of rail and additional copper for entire railroad.

MECHANICAL DESIGN. — The general design of the rail itself having been settled, the next step is to secure a set of track plans on which to lay out the special work. When an entirely new railway is being projected, the track designer and the third-rail designer can work together, but when an existing line is being converted, the general track plans cannot be used as they are seldom sufficiently accurate for the electrical engineer's purpose. In this case, the contact-rail engineer has to take measurements of the track work in order to make drawings of the cross-overs and other complications.

Location and Weight of Third Rails. — There is no standard gage for contact rails, corresponding to the standard track gage. This unfortunate condition arises from lack of uniformity in the clearance lines of the right-of-way and in the maximum equipment lines of various railroads. The following standard has been recommended (1911 and 1912) by the American Electric Railway Engineering Association:

1. The gage line of the third rail to be located not less than 26 inches and not more than 27 inches from the gage line of the track and the contact surface of the third rail to be not less than 2¾ inches or more than 3½ inches above the plane of the top of the track rail.

2. The clearance lines for third-rail and permanent-way structures and rolling equipment to be as shown in Fig. 10, thus reserving the space within lines *AT, BT, CT, DT, ET, FT* and *AT, JT, KT, LT, MT* for third-rail structures; rolling equipment not to encroach upon the third-rail space under conditions of maximum wear and deflection beyond the line *AE, BE, CE, DE, EE, FE, GE* and permanent-way structures not to encroach upon the third-rail space beyond

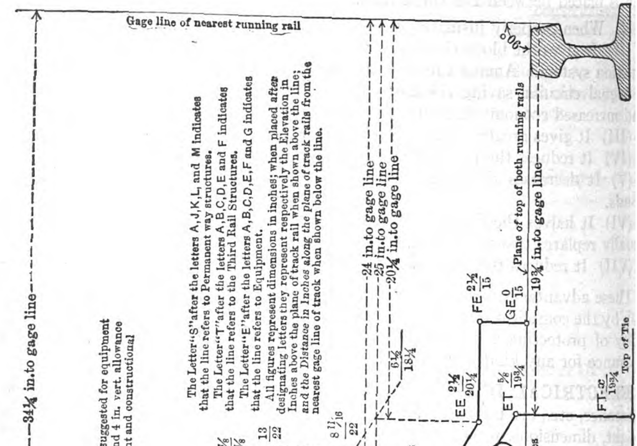


Fig. 10. Clearance Diagram

the line *AS, JS, KS, LS, MS*; this leaves a clearance space or neutral zone of one inch both horizontally and vertically upon which neither the third-rail structures nor equipment shall encroach. On curves of less radius than 800 feet, the third rail must be moved back and the equipment may be allowed to swing outward as indicated by the lines and notes on the diagram.

3. In the design and construction of new rolling stock to be used in interchange service allowance must be made for such horizontal and vertical variations as may in any reasonable probability occur in combination at one time, as

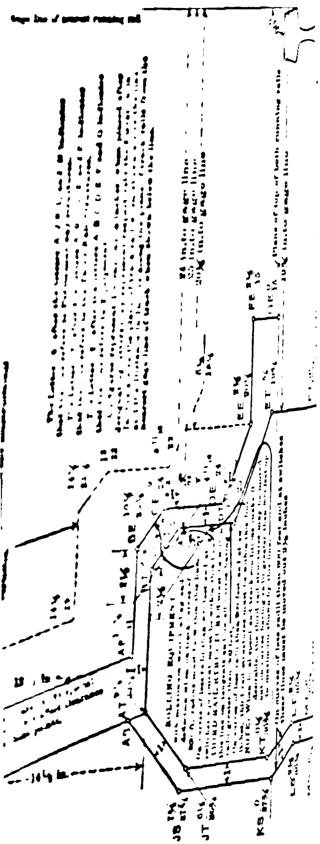

Fig. 10. Clearance Diagram

TABLE II. — LOCATION AND WEIGHT OF THIRD RAIL

well as allowance for deflections on curves. Encroachments on normal clearance due to deflection of springs and wear vary with the type of construction used, and the practice of the respective roads as regards permissible wear and deflection before repairs and adjustments are made. For the general guidance of the roads, in designing equipment, but not as a standard, therefore, a dotted line is shown on the diagram located two inches distant horizontally and four inches distant vertically from the limiting clearance line for equipment.

Table II gives the principal characteristics of the contact rails of many of the most important electric railroads.

Turnouts. — (*See also Railways, Location and Permanent Way for.*) A typical turnout is shown diagrammatically in Fig. 11 which shows the lengths which should be measured; F is the distance from the point of the switch to the point of the frog, and is called the "frog distance"; D is the length between the adjacent frogs, and Z the distance apart of the track centers. In such a diagrammatic view the lines represent the gage lines of the track rails. When, however, a contact rail is represented by a line, it is the center line that is given. Having measured the four distances specified above, the radius of the turnout curve may be calculated from the following formulas:

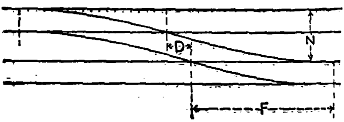

Fig. 11. Typical Turnout

$R = 0.127\ F^2$, when the turnout is from a straight track.

$R = 0.271\ F^2$, when the turnout is from a track of equal radius to the turnout.

Graphical Method of Locating Contact Rail. — The track plans having been drawn from the field sketches, to a scale of say ¼ inch to the foot, the contact rail may be drawn in, as outlined below. An aid in this work is an outline plan of the electric car or locomotive to the same scale as the track work drawings — say ¼ inch to the foot. Such a plan is shown in Fig. 12, in which the points W represent the wheels, S the contact shoes and K the king-pins. This had better be made of celluloid with a large pinhole at each point S. In order to lay out the contact rail the car is drawn along the tracks with the points W on the rails and a pencil stuck in one of the pinholes. The line traced by the pencil represents the center line of the shoe path, and therefore that of the contact rail. Such a line should be made on each side of the car. In cases where there are sharp curves, it will not do to run the wheel points W along the tracks, as an error will arise due to the truck rotation not being represented. In such a case the king-pin points must be run along a track center line.

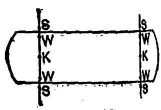

Fig. 12.

Location of Inclines. — The exact location of the contact-rail inclines on each side of a track-rail intersection depends upon a number of conditions, an important one of which is the extent to which the equalizer bar and journal box project outward. If there is a train-bus line connecting all the cars, the end inclines may be situated many feet back from the switch point or frog, but if there is no such bus line, the contact rail will probably have to be terminated in a cross incline extending as near as possible to the switch point or frog.

Isolated Section
Fig. 13.

Sectionalizing the Contact Rail. — Where a train-bus line is not used, it is customary to break the third rail in front of substations and use an isolated section of third rail between the two main sections, as

shown diagrammatically in Fig. 13. The length of this isolated section and of the gaps which bound it should be such that both gaps are never spanned by cars at the same time.

Let L = car length, feet,

T = distance between shoe centers (usually the same as distance between truck centers),

S = shoe length.

Then,

$$\text{Total space must be} > L + T + S.$$
$$\text{Rail section must be} < 2L - T - S.$$
$$\text{Length of each gap must be} < T - S.$$

For example, on the Manhattan Railway, New York, before a train-bus line was adopted, a short isolated section was used. The lengths were as follows:

$$L = 46.37, \quad T = 32.27, \quad S = 1.$$

Total space > 79.64, actually 83 feet.
Section of rail < 59.47, actually 57 feet.
Gap length < 31.27, actually 13 feet.

Cross and End Inclines. — Inclines serve the purpose of assisting the contact shoes to rise (or fall) from their free position to the position of contact with the rail. They should, therefore, have sufficient slope to prevent any undue shock either to the rail or to the shoes. Low-speed lines and sidings may therefore have shorter inclines than high-speed lines. The usual length of straight slope (i.e., without end nose and flat surface at top) is from 60 to 70 inches for high-speed work and 30 or 40 inches for sidings. The slope ranges from 1 in 45 for high-speed work to 1 in 30 for urban railways. Inclines are almost invariably made of cast iron. A typical design is shown in Fig. 14.

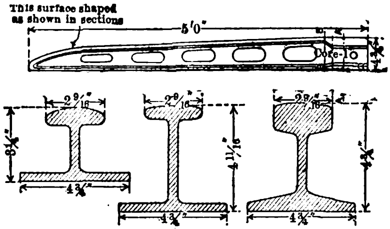

Fig. 14. Typical Incline

Third-rail Insulators. — Third-rail insulators should have the following qualifications. Strength to withstand weight and vibration; surface impervious to moisture; resistance wet shall not be less than one megohm; shall have a drip edge; shall allow free motion of rail laterally, longitudinally and vertically to allow for expansion, contraction and tie motion; and must be capable of easy and quick removal without disturbing the rail.

Spacing of Insulators. — A spacing of 10 feet between insulators is recommended by the American Street & Interurban Assn., Oct., 1908, for 30-foot rails.

INSTALLATION OF CONTACT RAIL. — In the case of an existing railway being electrified, the first step is to replace standard ties at proper intervals by long ones. A man then proceeds along the line with a template and marks the location of the screw holes of the insulator bracket. He is followed by an augur gang which drills the holes. Meanwhile the brackets (in the case of an under-contact rail) or the stool and insulators (in the case of a top-contact rail) are distributed along the line, and a gang following the augur gang screws the brackets or stools to the ties.

Where the rails rest on tie plates which have not yet penetrated the ties, it is not unusual to place shims under the brackets or stool until the tie plates have reached their normal position.

In the case of under-contact rails the brackets must be accurately checked for principal dimensions before being distributed.

The rails and fish-plates, etc., are next distributed along the line on that side of the track where they are to be installed and a gang follows which installs the rail, and, in the case of an under-contact rail, attaches the insulators and hook bolts; in the case of a top-contact rail, another gang follows, attaching the clips or whatever is used to fasten the rail to the insulators. Another gang follows to install the fish plates, expansion joints and anchorages, if any. If there are no anchorages or expansion joints, expansion and contraction are provided against by making an allowance at all joints, depending on the temperature at which the rails are installed. This is done by inserting an "expansion shim" while the rails are being bolted together. The thickness of shim for different temperatures on a 30-foot rail is given in Fig. 15.

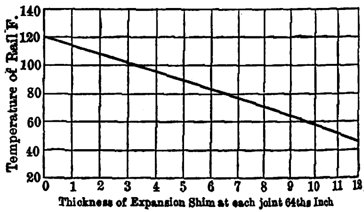

Fig. 15. Thickness of Expansion Shims for 30-ft. Rail

While the rails are being installed, the materials for the protection are distributed along the line and a gang follows installing them. A last gang paints the protection first with a priming and then with a finishing paint.

Inclines have to be carefully located to make sure that the shoes will ride smoothly upon them.

OPERATION AND MAINTENANCE OF CONTACT RAIL.—The wear of the third rails is negligible and even without painting the deterioration due to rust is very slow. The principal items of maintenance are the insulators, protection and bonds. Unless the supports are carefully designed, insulators are shattered by "tie motion," i.e., by the depression and rebound of the ties as the trains pass over them. Every time a wheel passes over a tie carrying an insulator, the latter is pounded against the rail and is likely to be broken unless sufficient play is provided.

Removal of Sleet.—The best protection against sleet is undoubtedly the under-contact third rail and the next best is a top-contact third rail with a wide protecting board. Where these are impracticable the deposit of ice on the rail cannot be prevented and means for its removal have to be adopted. The two principal means are scrapers and hot water. Electrical heating of the rail has also been suggested but found to require too much energy. When the hot-water method is used, some salt such as calcium chloride, or some other substance, which lowers the freezing point of water must be added to the water. There are serious objections to the hot-water method, especially on elevated railways, as the saline solution not only rusts the metal of the structure but when calcium chloride is used in the water, damage also occurs to the roofs of street cars, etc., underneath.

TESTING OF CONTACT RAILS.—Contact rails have to be tested for (1) electrical continuity at the joints, (2) conductivity, (3) insulation from ground and (4) gage.

Tests of Continuity at Joints are described in the article on *Bonds, Railway Track.*

The Conductivity Test is best performed by passing a considerable current through a length, measuring the drop with a milli-voltmeter and calculating the resistance by Ohm's law.

The Insulation Test is best performed by means of a pair of voltmeters, as shown in Fig. 16. The rail A to be tested is connected to a live rail B through a voltmeter, and the voltage V_1 between the two noted. At the same instant the voltage V_2 between the rail B and ground is also read. Let L be the length in miles of the rail A. Then the insulation resistance of the rail A in megohms per mile is

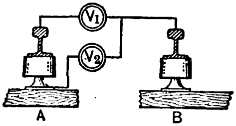

Fig. 16.

$$\frac{rL}{10^6}\left(\frac{V_2}{V_1} - 1\right),$$

where r is the resistance in ohms of the voltmeter on which V_1 is read.

Testing of Gage. — The gage line of a third rail is measured by means of a template which fits over the track rails as shown in Fig. 17.

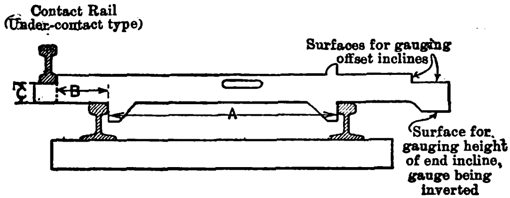

Fig. 17.

COST OF CONTACT-RAIL CONSTRUCTION. — The estimates in Table III include the cost of (1) handling and distributing the material from the storehouse to the place where it is used; (2) the solder, gasoline, etc., used in bonding contact rail; (3) putting three coats of paint on the protection; (4) bending rails on curves; (5) 5 per cent for breakage; (6) foremen's and engineers' salaries. They do not include the cost of tools or of jumpers.

These estimates are approximately correct where existing traffic does not materially impede the work. Under less favorable conditions, the cost may rise 50 per cent or more over the figures given.

The estimate on the top-contact type is based upon the Interborough Rapid Transit Co's. construction, New York (Stillwell-Slater patent), the weight of rail, however, being slightly less than on that railway. The estimate of the under-contact type is based upon construction similar to that used by the New York Central Railroad (Wilgus-Sprague patent).

TABLE III.—COST PER MILE OF CONTACT-RAIL CONSTRUCTION

Item	Top contact		Under contact	
	Amount	Cost	Amount	Cost
Material:				
Rail, 70 lb.	55 tons	$1815	55 tons	$1815

[W. A. DEL MAR.]

TIMBER. — (*See also Structures, Simple; Poles for Overhead Lines.*) The standard names for structural timbers as adopted by the Am. Soc. for Test. Mat. and the Am. Ry. Eng. Assoc. are reprinted below by permission from the present (1913) board of the Am. Soc. for Test. Mat.

Fir, Douglas. — The term "Douglas Fir" is to cover the timber known likewise as yellow fir, red fir, western fir, Washington fir, Oregon or Puget Sound fir or pine, norwest and west coast fir.

Hemlock, to cover Southern or Eastern hemlock; that is, hemlock from all states east of and including Minnesota.

Hemlock, Western, to cover hemlock from the Pacific coast.

Larch, Western, to cover the species of larch or tamarack from the Rocky Mountain and Pacific coast regions.

Pine, Norway, to cover what is known also as "Red Pine."

Pine, Southern Yellow. — Under this heading two classes of timber are used, (*a*) *Longleaf Pine*, (*b*) *Shortleaf Pine.*

It is understood that these two terms are descriptive of quality, rather than of botanical species. Thus, shortleaf pine would cover such species as are now known as North Carolina pine, loblolly pine and shortleaf pine. Longleaf pine is descriptive of quality, and if Cuban, shortleaf, or loblolly pine is grown under such conditions that it produces a large percentage of hard summer wood, so as to be equivalent to the wood produced by the true longleaf, it would be covered by the term "Longleaf Pine."

Pine, Western, to cover the timber sold as white pine coming from Arizona, California, New Mexico, Colorado, Oregon and Washington. This is the timber sometimes known as "Western Yellow Pine," or "Ponderosa Pine," or "California White Pine," or "Western White Pine."

Pine, White, to cover the timber which has hitherto been known as white pine, from Maine, Michigan, Wisconsin and Minnesota.

Pine, Idaho White, the variety of white pine from western Montana, northern Idaho and eastern Washington.

Redwood, to include the California wood usually known by that name.

Spruce, to cover Eastern spruce; that is, the spruce timber coming from points east of Minnesota.

Spruce, Western, to cover the spruce timber from the Pacific coast.

Tamarack, to cover the timber known as "Tamarack," or "Eastern Tamarack," from states east of and including Minnesota.

A fuller description of the timbers used for transmission line poles is given in the article on *Poles for Overhead Lines.*

DEFECTS IN TIMBER. — The standard names for defects in structural timber as adopted by the above associations are the following:

Encased Knot. — An encased knot is one which is surrounded wholly or in part by bark or pitch. Where the encasement is less than ⅛ inch in width on both sides, not exceeding one-half the circumference of the knot, it shall be considered a sound knot.

Large Knot. — A large knot is a sound knot, more than 1½ inches in diameter.

Loose Knot. — A loose knot is one not firmly held in place by growth or position.

Pin Knot. — A pin knot is a sound knot not over ½ inch in diameter.

Pith Knot. — A pith knot is a sound knot with a pith hole not more than ¼ inch in diameter in the center.

Rotten Knot. — A rotten knot is one not as hard as the wood it is in.

Round Knot. — A round knot is one which is oval or circular in form.

Sound Knot. — A sound knot is one which is solid across its face and which is as hard as the wood surrounding it; it may be either red or black, and is so fixed by growth or position that it will retain its place in the piece.

Spike Knot. — A spike knot is one sawn in a lengthwise direction; the mean or average width shall be considered in measuring these knots.

Standard Knot. — A standard knot is a sound knot not over 1½ inches in diameter.

Pitch Pockets. — Pitch pockets are openings between the grain of the wood containing more or less pitch or bark. These shall be classified as *small*, *standard* and *large* pitch pockets.

(*a*) *Small Pitch Pocket.* A small pitch pocket is one not over ⅛ inch wide.

(*b*) *Standard Pitch Pocket.* A standard pitch pocket is one not over ⅜ inch wide, or 3 inches in length.

(*c*) *Large Pitch Pocket.* A large pitch pocket is one over ⅜ inch wide, or over 3 inches in length.

Pitch Streak. — A pitch streak is a well-defined accumulation of pitch at one point in the piece. When not sufficient to develop a well-defined streak, or where the fiber between grains, that is, the coarse-grained fiber, usually termed "Spring wood," is not saturated with pitch, it shall not be considered a defect.

Shakes. — Shakes are splits or checks in timbers which usually cause a separation of the wood between annual rings.

Ring Shake. — An opening between the annual rings.

Through Shake. — A shake which extends between two faces of a timber.

Rot, Dote and Red Heart. — Any form of decay which may be evident either as a dark red discoloration not found in the sound wood, or the presence of white or red rotten spots, shall be considered as a defect.

Wane. — Wane is bark, or the lack of wood from any cause on edges of timbers.

DECAY AND PRESERVATION. — Decay is due usually to a fungus growth. It is prevented by cutting off the air by immersing the timber in water, which so far as is known is a sure preventive. Decay is retarded by thorough seasoning either naturally or in the kiln, or by poisoning the food supply of the fungus by chemical treatment. The latter method usually consists in impregnating the wood with creosote or zinc chloride, the former being more commonly employed. The methods used for preserving timber poles are described in the article on *Poles for Overhead Lines*.

UNIT STRESSES FOR STRUCTURAL TIMBER. — The values of unit stresses in structural timber given in the following table are recommended by the Committee on Wooden Bridges and Trestles of the American Railway Engineering Association. See *Manual* of the Association, Chicago, 1911. For unit values allowable in various cities of the United States see article on *Buildings, Allowable Unit Stresses in.*

UNIT STRESSES FOR STRUCTURAL TIMBER IN POUNDS PER SQUARE INCH

(*See Note under table*)

Kind of timber	Compression: Perpendicular to grain — Elastic limit	Compression: Perpendicular to grain — Working strength	Compression: Parallel to grain — Average ultimate	Compression: Parallel to grain — Working strength	Working strength of columns — Length under 15 diameters	Working strength of columns — Length over 15 diameters	Ratio of length of stringer to depth
Cedar, Red	470	230	2800	900	680	$900\left(1-\frac{L}{60D}\right)$	..
Cypress, Bald	340	170	3900	1100	830	$1100\left(1-\frac{L}{60D}\right)$	..
Fir, Douglas	630	310	3600	1200	900	$1200\left(1-\frac{L}{60D}\right)$	10
Hemlock, Western	440	220	3500	1200	900	$1200\left(1-\frac{L}{60D}\right)$	..
Oak, White	920	450	3500	1300	980	$1300\left(1-\frac{L}{60D}\right)$	12
Pine, Longleaf	520	260	3800	1300	980	$1300\left(1-\frac{L}{60D}\right)$	10
Pine, Norway	....	150	2600*	800	600	$800\left(1-\frac{L}{60D}\right)$	..
Pine, Shortleaf	340	170	3400	1100	830	$1100\left(1-\frac{L}{60D}\right)$	10
Pine, White	290	150	3000	1000	750	$1000\left(1-\frac{L}{60D}\right)$	10
Redwood	400	150	3300	900	680	$900\left(1-\frac{L}{60D}\right)$	..
Spruce	370	180	3200	1100	830	$1100\left(1-\frac{L}{60D}\right)$	..
Tamarack	....	220	3200*	1000	750	$1000\left(1-\frac{L}{60D}\right)$	..

* Partially air dry.

L = unsupported length in inches. D = least side in inches.

NOTE. — These unit stresses are for a green condition of timber and are to be used without increasing the live-load stresses for impact.

The working units given in these tables are intended for railroad bridges and trestles. For highway bridges and trestles the unit stresses may be increased twenty-five (25) per cent. For buildings and similar structures in which the timber is protected from the weather and practically free from impact, the unit stresses may be increased fifty (50) per cent. To compute the deflection of a beam under long-continued loading instead of that when the load is first applied, only fifty (50) per cent of the corresponding modulus of elasticity given in the table is to be employed.

UNIT STRESSES FOR STRUCTURAL TIMBER IN POUNDS PER SQUARE INCH

(*See Note bottom of p. 1589*)

Kind of timber	Bending: Extreme fiber stress		Bending: Modulus of elasticity	Shearing: Parallel to grain		Shearing: Longitudinal shear in beams

* Partially air dry.

STANDARD SIZES. — The commercial sizes of spruce and yellow pine in the eastern part of the United States are as follows:

Spruce. — Cross-sectional dimensions in inches are:
2 by 3, 2 by 4, 2 by 5, 2 by 6, 2 by 7, 2 by 8, 2 by 10, 2 by 12
3 by 4, 3 by 6, 3 by 8, 3 by 10, 3 by 12
4 by 4, 4 by 6, 4 by 8, 4 by 10, 4 by 12
6 by 6, 6 by 8, 6 by 10, 6 by 12
8 by 8, 8 by 10, 8 by 12.
12 ft. to 22 ft. are ordinary lengths.
23 ft. to 26 ft. are less common.
27 ft. to 32 ft. are obtained with difficulty.

Yellow Pine. — Same cross-sectional dimensions as spruce and also the following (dimensions in inches):

2 by 14, 2 by 16	6 by 14, 6 by 16	12 by 14, 12 by 16
3 by 14, 3 by 16	8 by 14, 8 by 16	14 by 14, 14 by 16
4 by 14, 4 by 16	10 by 14, 10 by 16	16 by 16

Yellow pine sticks are commonly longer than spruce sticks, frequently exceeding 40 ft.

DESIGN OF TIMBER BEAMS. — Timber beams may be designed by the application of the ordinary beam formulas (*see Design of Beams in article on Structures, Simple*). Timber is especially weak in longitudinal shear which is the determining factor in many cases as shown by the preceding tables. It should, however, be noted that the projection of the end of a beam over the end supports often gives the timber a greater resistance to shear than would be allowed by the strict application of theory and the designer must often use considerable discretion in applying the shear formula.

ALLOWABLE LOADS (POUNDS) ON BEAMS OF LONGLEAF YELLOW PINE

(See Note below table)

Allowable uniformly distributed load in pounds per inch width per lineal foot, in excess of weight of beam, for end-supported yellow pine beams, supported laterally at intervals of 12 times their thickness or less. *Tabular values to be multiplied by width of beam in inches to get carrying capacity of beams per lineal ft.*

Span in ft. = distance c. to c. end bearings	Depth of beam in inches									Coefficient of deflection

NOTE.—The tables pp. 1591 and 1592 are for railroad structures of green timber and require no allowance for impact.

For highway structures add 25 per cent to tabular values.

For buildings and other structures where timber is protected from weather add 50 per cent to tabular values.

Bold-faced type is used for lengths where shear limits.

Values below zigzag line cause a deflection under intermittent load in excess of 1/360 of span.

For actual deflection in inches, except where strength is limited by shear, divide deflection coefficient by depth of beam in inches. Deflection under permanent load will ultimately equal double this value.

ALLOWABLE LOADS (POUNDS) ON SPRUCE BEAMS

(*See Note, bottom p. 1591*)

Allowable uniformly distributed load in pounds per inch width per lineal foot, in excess of weight of beam, for end-supported spruce beams, supported laterally at intervals of 12 times their thickness or less. ***Tabular values to be multiplied by width of beam in inches to get carrying capacity of beams per lineal ft.***

Span in ft. = distance c. to c. end bearings	Depth of beam in inches									Coefficient of deflection
	4	5	6	7	8	10	12	14	16

25	....	....	....	....	....	16	23	32	43	14.31
26	....	....	....	....	....	14	21	29	39	15.48
27	....	....	....	....	....	13	19	27	36	16.70
28	....	....	....	....	....	12	17	25	33	17.96
29	....	....	....	....	....	....	16	23	31	19.26
30	....	....	....	....	....	....	15	21	29	20.61

The unit values used in the tables are:

Yellow Pine	Lb. per sq. in.	*Spruce*	Lb. per sq. in.
Fiber stress:		Fiber stress:	
Bending	1,300	Bending	1,000
Longitudinal shear	120	Longitudinal shear	70
Modulus of elasticity	1,500,000	Modulus of elasticity	1,310,000

These unit values used are the same as given in the table on pp. 1589 and 1590, except the modulus of elasticity for Yellow Pine, which is taken as 1,500,000 lb. per sq. in. For other values of stress modify tabular values in proportion to allowable unit stresses.

WEIGHT OF TIMBER. — This is variable, depending upon the moisture in the timber and whether it has been chemically treated or not. It is common to assume yellow pine at 4½ lb. per board foot and spruce at 4 lb. per board foot in estimating the strength of beams. See also section on *Volume and Weight of Poles* in article on *Poles for Overhead Lines*.

COST OF TIMBER. — The price of timber is variable and depends for ordinary stock upon the size and length. Yard quotations in New York in June, 1913, gave the price of spruce as from \$35 to \$37 per 1000 board feet. Similar quotations on longleaf yellow pine were as follows:

COST OF YELLOW PINE IN DOLLARS PER 1000 BOARD FEET AT YARD IN NEW YORK

Cross section	Length of stick			
	20 feet and under	21 to 25 feet	26 to 30 feet	31 to 35 feet
2 in. thick by 8 in. wide, and under..	\$36	\$36	\$36	\$38
10 in. thick by 10 in. wide, and under..	42	42	42	45
12 in. thick by 12 in. wide, and under..	42	42	42	45
14 in. thick by 14 in. wide, and under..	47.50	48	50	50
16 in. thick by 16 in. wide, and under..	50	52	54	60

For regular quotations on timber see the first issue of each month of the *Engineering News*.

The cost of hauling timber and putting in place may be roughly estimated at \$10 per 1000 board-feet for fairly heavy yellow pine timbers which require little labor.

TOWERS FOR TRANSMISSION LINES. — (*See also Distribution Lines; Insulators for Transmission Lines; Poles for Distribution Lines; Structures, Simple; Transmission Lines.*) Steel towers are used as a substitute for wooden poles for supporting electrical circuits. They have the advantages over poles that they can be of as large size as desired and are much more permanent. Steel towers are especially advantageous for high voltages (over 50,000) where wide wire spacing is necessary; for long spans, such as river crossings, where the mechanical stresses are exceptionally heavy; and in localities where grass, brush or forest fires occur.

GENERAL FEATURES OF DESIGN. — Towers are composed of two parts, the tower proper and the foundation. Towers are usually built of standard structural steel shapes. Angles are used for most members. Channels are used for the larger members of some towers, usually the cross arms, or for posts of flexible towers. Flat pieces are sometimes used for the minimum-sized bracing of light towers. Round rods are used for tension members in some types. The principal members of a tower are the corner posts or legs, which are vertical or approximately vertical, and are usually the heaviest members of the tower proper, and the horizontal and diagonal web members which connect the posts together in vertical planes which constitute the sides or faces of the tower.

The spread of a tower at the base is generally between one-fourth and one-fifth of the height. The greatest economy in cost of tower plus foundation usually requires a little wider base than that which gives the least cost for the tower taken alone.

Towers are usually designed for either one or two three-wire circuits, usually with one or two ground wires above and sometimes with a telephone circuit below. Where two circuits are on one tower they are usually located on opposite sides to reduce the hazard of repairing the line. The three wires of a circuit are occasionally arranged to form an equilateral triangular prism, but frequently lie in a single plane which is usually horizontal for single-circuit towers, and vertical for two-circuit towers.

Types of Towers. — There are two general types of towers, viz., (1) the flexible, having only two legs and (2) the rigid, having three or more legs.

Flexible Towers (Fig. 4). — The flexible tower is set with face at right angles to the line so as to rigidly resist any transverse force, such as a wind blowing across the line, while bending if necessary to relieve any stress in the direction of the line. The stability of the tower in the direction of the line is maintained by the conductors which it supports acting as guys. Where conductors cannot perform this function, due to being attached by suspension insulators, the ground wires are used as the guys. The flexible tower is especially economical in the smaller sizes, where the line conditions approximate those where wooden poles would otherwise be used. On lines of flexible towers, rigid anchor towers are set at intervals.

Rigid Towers. — These are usually triangular, square (Fig. 2) or rectangular (Fig. 3). The square tower is probably the most common. Square towers usually have the four faces framed with the same size members (even though the stresses in the longitudinal and lateral faces rarely figure the same), because of the economy of manufacture and erection which results from the simplicity. This feature has an advantage in design in that the torsional stresses are more simply determined. Rectangular (including square) towers have the disadvantage that the unequal settlement of the foundations may produce high internal stresses not allowed for in the design. Triangular towers avoid internal stresses from unequal foundation settlement, but present diffi-

culties in the joining of standard structural shapes, and stresses in them are difficult to calculate.

Connections of Members. — The members of a tower are usually connected by bolts. By using no rivets the members may be compactly bundled, easily handled even in rough country, erected by less skillful labor and the galvanizing can be done after all shop work is completed. All the bolts of a tower should be of one diameter (5/8 inch is suitable for the members generally used) and of as few different lengths as possible. Bolt holes should be slightly larger than the bolts (1/16 inch is a usual amount). By designing bolted connections so that friction between the surfaces develops the full compressive strength of members, the play in the bolt holes with changing compression and tension in the members is eliminated.

Clearance Between Conductors and Tower. — The clearance between conductor and tower should be sufficient so that the current will not jump to the tower at a lower voltage than is required to arc over the insulator. This is usually determined approximately by making the clearance equal or exceed the length of the string of suspension insulators. Allowance must also be made for change of position of conductor with swing of suspension insulator. The amount of swing will not ordinarily exceed 45 degrees from the vertical, but should be determined for each case with and without ice loading; see *Transmission Lines*. The angle of swing will be greater for small than for large conductors and will be more for aluminum than for copper of the same diameter. Clearance to the cross arm will require special consideration where the angle of swing exceeds 45 degrees from the vertical and also for lesser angles where insulators are used which do not have an arc-over voltage very high compared to the working voltage.

Foundations for Towers (Figs. 5 and 6). — Structural steel, mass (unreënforced) concrete, reënforced concrete or piles may be used for tower foundations. Rock footings are also used in special locations.

Structural Steel Foundations are cheap and easily transported. While their durability has been questioned, they have been widely used without much trouble on this account yet apparent.

Concrete Foundations have an advantage over structural steel in that they can more easily be varied in depth, spread, etc., to accommodate themselves to local conditions of soil. This is especially advantageous where boulders or irregular ledges interfere with the use of a standard-sized foundation.

Mass-concrete foundations are advantageous in those cases where it is necessary or desirable to have a foundation of such weight as to withstand much uplift with little reliance on the holding power of the earth. The towers may be conveniently attached to anchor bolts imbedded in the foundation. To avoid tension in the concrete the bolts must extend to the bottom, with proper plates for distributing the stress. The anchor bolts and plates then become a crude system of reënforcement.

Reënforced concrete foundations are durable and require less material than mass concrete, thereby facilitating transportation.

Piles are used under or for foundations in very marshy ground where the holding power of other foundations is unreliable.

Rock Footings for towers standing on ledges may consist of anchor bolts grouted into holes drilled in rock and extending through level bearing plates grouted to the rough rock surface at the proper elevation.

FORCES ACTING ON TOWERS. — The stresses in towers are caused by: (1) The weight of tower, insulators, clamps, cables (conductors, ground wires,

telephone wires) and ice loads on them; (2) The wind pressure on above;* (3) The unbalanced tension in cables when dead ended or broken on one side; (4) The unbalanced resultant due to cable tension at angles in the line; (5) The loads imposed when erecting towers, stringing wire or repairing line.

A careful study should be made of all the combinations of these loads which are possible or probable. Often no single combination can be found which will produce the maximum stress in all tower members, and therefore several combinations must be used to determine the design.

In a square anchor tower carrying six wires, three on each side, the maximum stress may be expected in the corner posts when all six wires are pulling in the same direction; the maximum stress in the web members will probably be produced by three wires pulling on one side in one direction and the three on the other side in the opposite direction. In the first case the tower is subject to a bending stress and in the second to a torsional stress. In each case the stresses due to weight and wind are to be superimposed. The wind may act as a force along the line or across the line, but generally its longitudinal effect is negligible while its lateral effect is important.

Stresses in Tower Members. — The stresses in the several members of a tower are usually determined graphically from the assumed loadings by means of stress diagrams; see section on *Trusses* in the article on *Structures, Simple*. In most designs the distribution of stress is not fully determinate.

Fundamental Assumptions. — Certain assumptions are, however, commonly made which give a determinate distribution for the purposes of design. Among these assumptions are:

(1) An unbalanced stress on the tower (say a broken wire pulling on one side) can be resolved into an equal stress at the axis of the tower and a torsional moment.

(2) The equivalent stress at the axis of a rectangular tower can be considered as balanced between the two faces parallel with it, each face taking one-half the stress.

(3) The torsional moment can be considered as divided between all four faces of a rectangular tower.

(4) If the tower is square each face takes one-fourth of the torsion.

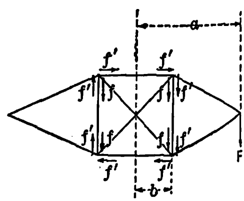

Fig. 1.

The above relations may be expressed as follows, (see Fig. 1):

Let F = unbalanced force in pounds applied at end of cross arm,
a = distance, in feet, from *end of cross-arm* to axis of tower,
b = distance, in feet, from *side of tower body* to axis of tower;

then

$$f = \frac{F}{4} = \text{balanced force in pounds applied at each corner post equivalent to } F \text{ in bending effect on body of tower,}$$

* The wind pressure on a tower is assumed to be uniformly distributed per square foot of surface against which the wind blows, one-half of it consequently being on the windward side of the windward face and the other half on the windward side (inside) of the leeward face. For simplicity in calculation this uniformly-distributed force is replaced by a series of concentrated forces, one at each panel point equivalent to the total distributed force extending over a half panel above and a half panel below the panel point. By panel point is meant a point of intersection of principal members, for example, of horizontal members with vertical members in Fig. 4; and by panel is meant the section of a side between panel points, a panel usually being bounded by two vertical and two horizontal members as in Fig 4.

$f' = \dfrac{Fa}{8b}$ = torsional force in pounds applied at each corner post equivalent to F in twisting effect on body of tower.

(5) In a tower framed with a double system (i.e., diagonals in duplicate and suitable for compression as well as tension) each system may be considered as taking one-half of the stress as far as possible.

Approximations Made in Calculating Tower Stresses.— The stress diagrams are usually simplified by employing certain approximations:

(a) Faces of towers are usually battered so that they deviate slightly from a true vertical plane, but the stress diagrams usually neglect this inclination and are based on the vertical projection of the face.

(b) Where the face of a tower does not lie in one plane (i.e., has a change of batter as occurs frequently at bottom cross arm where a prismatic cage joins a pyramidal base) the change of inclination is neglected and the diagrams are based on a single vertical projection as before.

Subject to the limitations of the assumptions and approximations given above, the four faces of the tower can be regarded as four cantilevers, supported at the base and loaded at the top, which are independent except that the four corner posts are each common to two faces and must contain the resultant of both stresses.

Where a face of a tower or any part of a face has any considerable inclination the above approximations may not be used without danger of serious error.

Unstressed Members. — A tower usually contains members no stress in which is shown by the stress diagram, viz.:

(1) Diagonal members in a horizontal plane do not usually appear in the stress diagram when located below the lowest cross arm. These members play an important part in the distribution of torsion among the faces. In a rectangular tower the torsion will usually redistribute between the four faces at each level where there are horizontal diagonals, therefore the failure of the stress diagram to show stresses in them may be taken to indicate that the assumed distribution of torsion is not quite correct rather than a true absence of stress.

(2) Redundant members are braces which carry no determinate stress but perform the important function of supporting the compression members which do carry stress. The unit stress allowable in a compression member diminishes as the unsupported length increases. The weight of compression members is therefore diminished by dividing their unsupported length by braces applied at one or more intermediate points.

Unit Stresses in Towers. — The factors of safety and unit stresses used in tower design have not been standardized. In some cases it has been assumed that the combination of loading taken for tower design represented conditions which would happen so rarely that a tower which would stand these loadings in test without failure would be sufficient. This is equivalent to taking a severe combination of loads and designing for a factor of safety of but one. The result, however, may be as good a tower as one designed for the same conditions individually (but not in combination) with a factor of safety of two or four. It is probable that few towers are designed for the combination of all loadings, each taken at the most severe condition reasonably possible with an actual factor of safety exceeding two.

For a factor of safety of from $2\frac{1}{2}$ to $1\frac{1}{2}$ (as determined by test of completed tower, not of individual members) the following unit stresses have been used:

Tension: 12,000 to 20,000 lb. per sq. in.
Shear: 12,000 to 20,000 lb. per sq. in.
Bearing: 16,000 to 30,000 lb. per sq. in.
Compression: $12{,}000 \div K$ to $20{,}000 \div K$ lb. per sq. in.

Where

$$K = \frac{L^2}{36{,}000\,R^2},$$

L = unsupported length of member, in inches,
R = least radius of gyration of section, in inches,

L and R are so limited that for main members $L \div R$ does not exceed 125 to 180 and for secondary members $L \div R$ does not exceed 150 to 220.

Eccentricity in Stresses at Joints. — As tower members are ordinarily connected together the stresses in them are slightly eccentric, thereby preventing the full strength of the members being developed. The eccentricity should be eliminated or reduced as much as possible by having the center of gravity of the several members at each connection meet at one point as exactly as possible.

FORCES ACTING ON TOWER FOUNDATIONS.—Foundation stresses are of two classes: first, the foundations resist the tendency of the tower to slide and overturn due to the external forces on it considering the tower as a self-contained structure; second, the foundations resist certain stresses which would be internal tower stresses were the tower framed as a complete self-contained structure, but which become external stresses because the ground is depended on for the function of certain omitted members. The weight of the tower can evidently be reduced by thus substituting the ground for certain members, but the size of foundation is thereby increased. The amount of these latter stresses depends on the outline and framing of the tower and their effect should not be overlooked in determining loadings on foundations.

The magnitude and direction of the forces acting on the tower foundations may be illustrated by taking the case of a rectangular tower, and considering a transmission line which runs north and south.

Let

a = width (feet) of base of tower (east and west);
b = length (feet) of base of tower (north and south);
W = total weight (pounds) of tower, insulators, fittings and one span of all the wires, including ice load, if any;
W' = total weight (pounds) of any unbalanced load, such as a wire c feet off center;
F = resultant force (pounds) of the wind on the tower and a complete span of all the wires (with ice coat, if any), acting at a distance of d feet above the foundation, wind assumed blowing across line from west to east,
P = pull (pounds) of any unbalanced force toward the south applied at a distance of e feet above the foundation and f feet to the west of axis of tower, as for example, a dead-ended wire or when a wire on the north side of the tower is broken.

Then, assuming that the forces divide equally among the four foundations and that the torsional forces are in a circumferential direction, the relations given in the following table hold. These assumptions are reasonably correct for a tower with the four legs joined at the bottom with a horizontal strut in each of the four faces and with horizontal ties across the diagonals, unless the framing which is usually provided in the other faces is inadequate. Probably few towers in use fully meet these requirements. Therefore, there are usually additional stresses of large magnitude due to the foundations performing the function of missing or inadequate members, as pointed out in the notes appended to the table.

FORCES ON TOWER FOUNDATIONS

Magnitude of force on each of the four foundations	Direction at each foundation			
	N. E. corner	S. E. corner	S. W. corner	N. W. corner
$\frac{W}{4}$	Down	Down	Down	Down
$\frac{cW'}{a}$	Down	Down	Up	Up
$\frac{F}{4}$ (Note 1)	East	East	East	East
$\frac{dF}{a}$	Down	Down	Up	Up
$\frac{P}{4}$ (Note 2)	South	South	South	South
$\frac{eP}{b}$	Up	Down	Down	Up
$\frac{afP}{4(a^2+b^2)}$ (Note 3)	North	North	South	South
$\frac{bfP}{4(a^2+b^2)}$ (Note 3)	West	East	East	West

NOTES. — Where there are no struts between the bottoms of the legs, and especially where the bottom panel is framed on the single system, both of which conditions are usual:

(1) The force of the wind F will give a greater force than $F/4$ in an easterly direction on the two west foundations and a correspondingly less force on the other two, and will in addition produce four new forces tending to force the legs apart on the compression side and draw them together on the tension side.

(2) Similarly the pull of the wire P will give a greater force than $P/4$ in a southerly direction on the two north foundations and a correspondingly less force on the other two, and will in addition produce a westerly force at the N. E. and S. W. corners and an easterly force at the S. E. and N. W. corners.

(3) Similarly, the torsional forces due to P will increase in magnitude and change in direction, and the unbalanced pull P may develop new forces tending to raise two diagonally-opposite legs and depress the other two.

Resultant Forces on Foundations. — From the above relations the resultant force on each of the four foundations may be found. In general there will be on each foundation: (1) a downward pressure, (2) a direct uplift, and (3) a horizontal overturning force, producing a tendency to slide and an uplift on one side of the foundation and a downward pressure on the other side.

Downward Pressure. — The downward pressure usually is of little importance in determining the size of the foundation as a foundation large enough for uplift and overturning is unnecessarily safe against downward pressure.

Direct Uplift. — The uplift is very important, as the weight of tower and foundation is rarely sufficient to provide more than a small fraction of the holding-down power required. The excess uplift is usually resisted by the earth in which the foundation is buried. Not only is the weight of the earth directly over the foundation effective but there is an additional resistance due to friction or cohesion of the earth which may be several times greater. These forces are usually computed on the assumption that they are equivalent to the weight of the earth in a frustum of an inverted cone or pyramid covering the founda-

tion and extending to the surface of the earth. The face of this cone is usually taken as making an angle of 30° with the vertical.

Horizontal Overturning Force, Sliding and Indirect Uplift. — The horizontal overturning force is also important. Its effect on the base may be resolved into two components, one a horizontal force tending to slide the foundation and the other a moment tending to rotate the base about a horizontal axis. The resistance of the earth to these forces is an obscure subject, especially if the foundation is of irregular shape. The following discussion which neglects several favorable elements may be considered as a conservative view of the earth resistance.

The resistance to sliding may be considered as due to the friction of the bottom of the base on the earth, and it may further be assumed that any base large enough to resist uplift will also furnish sufficient friction to prevent sliding. The arm of the overturning force is then the same as the height of the foundation (bottom of base to top where tower is attached), and the overturning moment is equal to the horizontal force multiplied by this arm. The resisting moment may be considered as due entirely to the vertical reaction of the earth on the top and bottom of the foundation. These vertical pressures may be taken as varying uniformly from zero at a horizontal neutral axis through the middle of the base, to a maximum at the edges of the base most remote from the axis. The moment of resistance is calculated as for a beam subject to bending and having a cross-section identical with the area of the base. It may be assumed that any unit pressure allowable on the uplift edge will be amply safe on the opposite edge where the pressure is downward, so that calculations for uplift only are necessary. The maximum allowable unit stress on the uplift edge may be taken as equal to the average unit resistance to uplift of the whole foundation, determined as described above under *Direct Uplift*.

Limiting Conditions. — Usually the most severe condition that a tower foundation is required to meet consists of a combination of uplift and overturning. For this condition the unit stress of uplift proper must be added to the maximum unit stress of uplift due to overturning and the sum must be within the allowable average unit resistance to uplift.

Strength of Foundations. — (*See also article on Strength and Elasticity.*) A foundation is subject to stresses from the tower tending to move it and from the resistance of the earth preventing motion. The foundation should of course be strong enough not to break when subject to these opposing forces. As the points of application of the resistance of the earth and the magnitude of the unit stresses transmitted by the earth at any point are subject to great uncertainty, the foundation should be designed for strength for the distribution of earth resistance which is most severe, considering for example that while the holding power is calculated on a uniformly-distributed earth resistance, it may be developed in practice by concentrated pressure from stones or timber located near the outer edge of the base.

Important Points Regarding Design of Foundations. — The following are important conclusions which follow from the above discussion:

(1) The inverted cone theory of resistance to uplift gives a calculated resistance which increases at a rapid rate with the depth (eventually increasing approximately as the cube of the depth). It would however be unsafe to apply the theory for foundations differing much from those of usual dimensions, say for depths much exceeding six feet and for foundations where the spread of base was much less than the depth to which it is buried.

(2) The foot of the tower (top of foundation) should be brought as close to the surface of the ground as possible to reduce the overturning moment.

(3) The tower diagonals of the bottom panel of the tower should intersect the corner posts as low as possible, because this is the actual point of application of the overturning force to the foundation and if this intersection is above the foundation this extra length must be added to the arm of the overturning moment.

(4) By inclining the axis of the foundation approximately in line with the inclined tower leg (i.e., to bring it as near as possible into line with the resultant of the horizontal overturning force and the vertical pressure or uplift) a more economical use of material may be made to resist the combined uplift and overturning.

TESTING OF TOWERS. — Since towers are generally indeterminate structures, new designs are usually tested. Test loads proportional to the loads specified for the design are applied until the required factor of safety has been proven or failure occurs. Towers are usually mounted on a rigid base for testing. This gives the strength which the tower would develop on an "ideal" foundation. In practice the tower must be expected to develop somewhat less strength, as unequal movement of the foundations will ordinarily overstrain certain members. Test loads may be applied by means of weights suspended directly at proper points for vertical loads and applied by means of pulleys attached to a tower-testing structure ("test tower") for horizontal loads. This method of application makes the determination of the test loads easy, but it is inconvenient to have the weights fall any considerable distance if the tower is tested to failure.

Testing of Foundations. — Foundations are occasionally tested, but the test is usually more for determining the holding power of the soil than the strength of the foundation. For the former purpose the test result will depend largely on the character of the soil and its condition (dry, wet or frozen). Tests for holding power are only necessary for uplift and overturning forces. In testing it is important that the testing machine should not press down on the surface of the soil near the foundation. The machine should rest on the ground outside of the base of an inverted cone of angle of 45° from the vertical and enveloping the base of the foundation under test.

SPECIFICATIONS, CONTRACTS AND PROPOSALS. — Different manufacturers of towers use different details of construction so that specifications written for the purpose of obtaining proposals should contain only conditions and requirements. These should state the loadings, factors of safety, maximum allowable stresses, and show outline dimensions of the tower as determined from clearances required.

The specifications should state whether towers are bolted or riveted, galvanized or painted, shipped assembled or partly assembled, tested or not tested, etc., besides containing the usual structural steel specifications; see *Steel.*

The proposals should show the arrangement and sizes of members and typical details of connections.

Contracts are oftentimes let on the basis of furnishing an approximate number of towers when the exact number required cannot be determined in advance, and a unit price per pound is included to cover extensions, special foundations and modifications that may be required.

The galvanizing and sherardizing of towers and parts are usually specified to pass the American Telephone and Telegraph Co's. Specification for galvanized iron wire (*see Galvanizing for Iron or Steel*). All members of towers that are not too heavy, so that there is danger of their buckling in the process, may be specified to be galvanized by the hot dip process. All bolts, nuts, threaded rods and turnbuckles may be specified to be sherardized.

INSTALLATION AND ERECTION. — Towers are generally shipped entirely disassembled, all of the members for one tower being bundled together. The tower is usually assembled lying on its face on the ground adjacent to the foundation. When assembled it is temporarily braced when necessary (usually by struts between the legs at the base of the tower) and up-ended onto the foundations. For the latter operation temporary hinges connecting the two legs lying on the ground to the two adjacent foundations are convenient. Towers too heavy to up-end and towers in inaccessible places are built up in place.

With bolted connections the nuts should be prevented from working loose by checking threads on bolts, riveting over the end of the bolt, or by lock-nut or washer.

Each tower member should have a number which should be shown on the erection drawings and marked on the corresponding member of each tower.

The members should be cut, bent and punched to template so that the parts will be interchangeable and the assembled tower will fit the foundation prepared for it.

Preparation of Foundations. — Foundations should be set with their bases below the frost line. The hole should not be excavated deeper than necessary, so that the foundation may rest on undisturbed earth. If any of the several foundations of a tower rest on loose backfill, unequal settlement may be expected which may greatly weaken the tower. The hole should not be larger than necessary, as the backfill will be less effective than undisturbed earth in resisting uplift. The resistance of concrete foundations can sometimes be increased by digging a hole smaller in diameter than the base and undercutting it at the bottom, while with structural steel foundations large stones can sometimes be placed against the steel to increase its resistance to motion, either vertical or lateral. The backfill should be well tamped in place and especial care should be used if it is probable that the foundation will be subject to heavy stress before the earth has had time to settle. On sloping ground filling may be required on the low side to give the designed weight of earth against uplift. In water or mud the floating power of hydrostatic pressure beneath the foundation must be allowed for. Where towers are raised on extensions the increased foundation stresses due to increased moment must not be overlooked.

The several foundations of a tower should be set accurately by template both as regards spacing and elevation so that towers stand trully vertical and have no initial stresses due to distortion.

MAINTENANCE OF TOWERS. — All bolted connections on towers should be carefully watched and kept tight, and the galvanizing or paint should be inspected regularly and towers must be repainted before any deterioration from rusting occurs. Foundations are the most likely source of trouble in operation. These should be kept properly backfilled and should be watched for unequal settlement of legs.

DIMENSIONS, WEIGHTS, COSTS. — Data on these items for a number of towers are given in the following table. Galvanized towers cost from 2½ to 4 cents per pound, f.o.b. factory. Galvanizing costs from ½ to 1 cent per pound; the cost of galvanizing is included in the figures just given.

TRANSFORMERS. — (*See also Alternating Currents; Auto-transformers; Electricity and Magnetism, Principles of; Standardization Rules of the A.I.E.E.; Transformers, Instrument.*) The following is a brief table of contents of this article:

General Description. — The electrical transformer, commonly called the static transformer, is a piece of stationary apparatus used to transform alternating-current energy at one voltage to some other higher or lower voltage. The single-phase transformer consists of two electrical circuits, usually of a large number of turns, interlinked with a common magnetic circuit of iron. Since the power is approximately the same in both windings, the currents in the two windings are inversely proportional to the voltages in the windings. The polyphase transformer is essentially two or more single-phase transformers made into a single piece of apparatus, but so designed that at least a part of the magnetic circuit is common to all the phases. A three-phase transformer has three high-tension and three low-tension windings arranged on a single iron core; see Figs. 1 and 2. The auto-transformer is treated in a separate article, viz., *Auto-Transformers.*

Terminology. — The winding by which the energy enters the transformer is logically the "primary" and the one by which the energy leaves the transformer is called the "secondary." Since either winding of the transformer may be connected to the source of energy, these terms are not definite unless the manner of connection is also stated. When referring to the transformer as a separate piece of apparatus the terms "high-tension" winding and "low-tension" winding are used to distinguish the two windings, the high-tension winding being the one with the greater number of turns. When the high-tension winding is connected to the source of supply it is the primary, and the transformer is said to be used as a "step-down" transformer; when the low-tension winding is connected to the source of supply, the high-tension winding is the secondary, and the transformer is said to be used as a "step-up" transformer.

CLASSIFICATION. — Transformers may be classified according to their operating characteristics, to their construction, or to the method of cooling.

Constant Potential and Constant-current Transformers.— Transformers may be either constant potential, such as are intended to give an approximately constant potential on the secondary side, or constant current, intended to give an approximately constant current on the secondary. Both types are intended to operate on a supply circuit of a constant potential.

Series Transformers are connected in series with the main circuit and receive a variable voltage and current in the primary. The secondary circuit is

closed through a path of low impedance and thus the secondary current will be proportional by the ratio of turns to the load current flowing in the primary or supply circuit. They are usually used to supply low-reading ammeters and wattmeters from circuits carrying very heavy currents.

Auto-Transformers or Compensators, sometimes called single-circuit transformers, consist of one electric circuit interlinked with the magnetic circuit and a tap brought off from some part of the winding. The voltage between this tap and either terminal of the electric circuit will be a fraction of the total voltage and thus a fractional voltage may be secured from this piece of apparatus. It is customary to proportion the windings on each side of the tap in accordance with the current to be carried. Auto-transformers are generally used where the ratio of voltages is quite near to unity as in this case they can be constructed with much less copper than the regular transformer. See article on *Auto-transformers*.

Potential Regulators are a form of transformer in which the voltage of one member may be varied from zero to a fixed maximum either by changing the direction of the magnetic flux or by changing the phase of the electromotive force of the secondary with respect to the electromotive force of the primary.

Core and Shell Types.—Two methods of arranging the electric and magnetic circuits are in use, the corresponding construction being designated as the "core type" or the "shell type." At present a large number of lighting transformers of small and medium capacity are constructed in a manner which is a composite of the core and shell types.

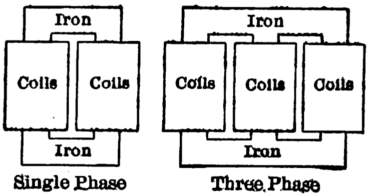

Fig. 1. Core-type Transformers

Core Type (Fig. 1).—The single-phase core-type transformer consists of a single magnetic circuit interlinked with two electric circuits, each consisting of a group of coils as shown in Fig. 1. The three-phase core-type transformer is also shown in Fig. 1.

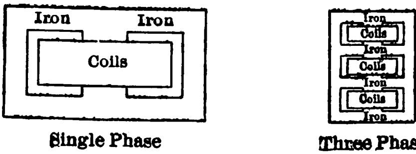

Fig. 2. Shell-type Transformers

Shell Type (Fig. 2).—In the shell type of transformer each electric circuit is interlinked with two magnetic circuits having a common path inside the coils but branching outside of the coils as shown in Fig. 2.

Comparison of Core and Shell Type.—The core type of construction is best adapted for high-voltage low-capacity transformers and the shell type for low-voltage high-capacity transformers. This arises from the fact that the most economical disposition of material in the core type demands a large number of turns and small cross-section of iron, while in the shell type a large cross-section of iron and small number of turns may be used to advantage. In the shell type the coils are usually wound in flat "pan-cakes," this type of construction being particularly well suited to the use of heavy copper rib-

bon or straps. In the core type the coils usually consist of two or more spools, long in comparison with their diameter. The use of the core type is increasing both in number and size of transformers as it is found possible to arrange the coils so they will better withstand the mechanical strain due to short circuits.

Classification According to Method of Cooling. — (*See also below.*) Transformers may be subdivided into classes in accordance with the method used for dissipating the heat due to their internal losses. As a transformer is a very compact piece of apparatus the problem of carrying away the heat is very important and various ingenious means have been devised for the purpose.

Naturally Cooled Transformers. — As this name implies this type of transformer has no special means of cooling but relies upon the ordinary circulation of the air. It is only used in transformers of very small sizes, such as those intended to supply meters.

Oil-cooled Transformers. — In this type of transformer the core and windings are submerged completely in oil in a tank and the windings and core are subdivided by ducts in order that the oil may circulate and carry off the heat from the internal parts. The heat is carried to the surface of the tank which contains the transformer and from there carried off by the surrounding air. The tank is specially designed to provide large air-cooling surfaces, e.g., provided with deep corrugations, or with projecting vanes or tubes.

Air-blast Transformers are designed with special passages through which a current of air is forced by means of a blower, the heat being carried off to the atmosphere in this manner.

Water-cooled Transformers consist of a construction similar to that of the oil-cooled type and in addition a coil of pipe carrying running water is submerged in the oil.

Forced-oil Transformers. — Transformers artificially cooled by circulation of oil are used when the size is too great for the self-cooling oil type and no cooling water is available. The oil circulates through external coils or tanks which give a greater cooling surface.

METHODS OF RATING. — The iron of transformers takes a long time to reach a constant temperature, that of oil-cooled transformers in particular requiring from 10 to 12 hours to reach a constant temperature. In the past, transformers have usually been rated in accordance with one of two following specifications; see, however, the *Standardization Rules of the A.I.E.E.* for the latest recommendations in regard to rating.

A-Rating. — The transformer will have a maximum temperature rise of 40° C. in continuous operation at normal load, and 55° C. rise at 25 per cent overload for two hours after reaching the maximum temperature at continuous normal load.

B-Rating. — The transformer will have a maximum temperature rise of 35° C. in continuous operation at normal load, and 55° C. rise at 50 per cent overload for two hours after reaching the maximum temperature at continuous normal load.

TRANSFORMER PRINCIPLES. — (*See also Electricity and Magnetism, Principles of.*) The essential features of a transformer consist of a primary winding having a number of turns interlinked with a magnetic circuit, and a secondary winding also interlinked with the same magnetic circuit, as shown in Fig. 3.

Simple Theory, Neglecting Leakage Reactance. — In the following discussion the assumption will first be made that all the flux links both primary and secondary windings; the effect of the leakage flux will be discussed later.

In Fig. 3, S_1 is the primary winding, M the magnetic circuit (of iron) and S_2 the secondary winding. If an alternating current is caused to flow in S_1 it will set up a flux in M which at any instant is proportional to the current i_1. Thus

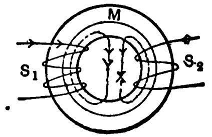

Fig. 3. Elementary Transformer

$$\phi = \frac{4\pi S_1 i_1}{10\,R},$$

where S_1 is the number of turns, i_1 the instantaneous value of the current and R the magnetic reluctance of the path in M.

Thus ϕ alternates with i_1 and since it interlinks with S_2 it will induce a voltage in S_2 at any instant equal to

$$e_2 = -\,S_2 \frac{d\phi}{dt}\,10^{-8} \quad \text{volts}$$

in which S_2 is the number of turns. The negative sign means that any current due to e_2 will tend to diminish ϕ.

No-load Conditions. — When there is no current in the secondary, the vector relations are as shown in Fig. 4. Let E_1 be the voltage impressed upon S_1, then the maximum value of the alternating flux will be

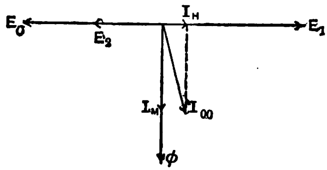

Fig. 4. No-load Relations

$$\phi = \frac{10^8 E_1}{4.44 f S_1},$$

where f is the frequency of alternation of E_1. Strictly, the numerator is $10^8(E_1 - r_1 I_{00})$, where I_{00} is the exciting current and r_1 the resistance of the primary, but the term $r_1 I_{00}$ is practically negligible. This flux will lag 90° behind E_1 or 90° ahead of the counter electromotive force E_c which it induces in S_1. The true magnetizing current I_m will be in phase with the flux and the hysteresis component of current I_H will be in phase with E_1. Hence the total no-load current I_{00} will assume some phase a little less than 90° behind E_1.

The flux ϕ will induce in the secondary turns S_2 an e.m.f. 90° behind the flux, hence 180° behind E_1 or in phase with the primary counter e.m.f. The effective value of this e.m.f. is

$$E_2 = 4.44 f S_2 \phi\, 10^{-8}.$$

Load on Secondary. — When the secondary is closed through a non-inductive external circuit a current will flow. This current will tend to demagnetize the iron, that is, to reduce the flux and hence the counter e.m.f. of the primary. This action, however, allows the current in the primary to increase until the secondary m.m.f. is balanced and there is left an excess m.m.f. in the primary to give sufficient flux to induce the counter e.m.f. E_1'. The vector relations are as shown in Fig. 5, again neglecting the leakage flux.

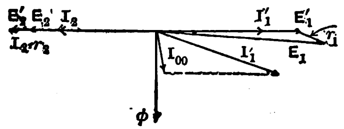

Fig. 5. Full Load, No Leakage

Leakage Reactance. — Due to the fact that a part of the lines of induction set up by the currents in the two windings pass through the air space (X in Fig. 3), the m.m.f.'s set up by the secondary current and the load current in

the primary (the current I_1' in Fig. 5) cannot neutralize each other, since the leakage fluxes established by the two currents are in the same direction, and not in opposition as are the fluxes in the iron. The primary leakage flux is in phase with the total primary current and the secondary leakage flux is in phase with the secondary current; these leakage fluxes are therefore not in phase with the useful flux (i.e., the flux which links both primary and secondary). The result is that the leakage fluxes cause a decrease in the secondary voltage and also a shifting of its phase with respect to the primary voltage.

Since the two leakage fluxes are in phase with the total currents in the primary and secondary respectively the voltages induced by the alternation of these fluxes are in quadrature with the currents. The quotient of the voltage induced in the primary by the alternating primary leakage flux divided by the primary current is called the "primary leakage reactance," and the quotient of the voltage induced in the secondary by the alternating secondary leakage flux divided by the secondary current is called the "secondary leakage reactance." These reactances are practically constants, since the major portion of the leakage path is in the air.

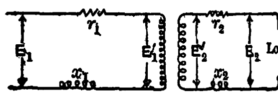

Fig. 6. Diagram of Circuits

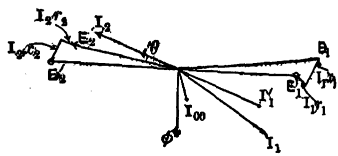

Fig. 7. Complete Vector Diagram

Complete Vector Diagram of Transformer.—Fig. 6 shows diagrammatically the primary and secondary windings of the transformer and Fig. 7 the vector diagram.

E_2 = the secondary terminal e.m.f.;
$\cos\theta$ = power factor of load;
I_2 = secondary current, lagging by angle θ behind E_2;
I_2r_2 = secondary resistance drop in volts; in phase with I_2;
I_2x_2 = secondary reactance drop in volts due to ½ of leakage flux, at 90° to I_2;
E_2' = induced e.m.f. in the secondary (hypothetical);
E_1' = e.m.f. necessary to overcome counter e.m.f. in primary; opposed and proportional to E_2' by ratio u;

$$u = \text{ratio of transformation} = \frac{S_1}{S_2};$$

I_1' = primary load current; opposed and proportional to I_2 by ratio $\frac{1}{u}$;
ϕ = mutual or useful flux;
I_{00} = primary no-load current;
I_1 = total or resultant primary current;
I_1r_1 = primary resistance drop; parallel to I_1;
I_1x_1 = primary reactance drop, at 90° to I_1;
E_1 = the required voltage on the primary, that is, the impressed e.m.f.

"Equivalent" Circuit of Transformer. — In practice it is not possible to measure separately the primary and secondary reactances. They must be measured together and treated as one quantity, called the total reactance x_t of the transformer, which may be expressed in terms of either the primary turns or the secondary turns.

A simple approximate method which is sufficiently accurate for all practical purposes is based on the equivalent circuits shown in Fig. 8. This method is

used in calculating the characteristics of a transformer from constants obtained from tests.

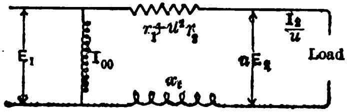

Fig. 8. Equivalent Circuit

Let E_2 = terminal e.m.f. of secondary;
$\cos\theta_2$ = power factor of load;
I_2 = secondary current;
u = ratio of transformation $= \dfrac{S_1}{S_2}$;
$E_2' = uE_2$;
$I_2' = \dfrac{I_2}{u}$;
R = total resistance in terms of primary $= r_1 + u^2 r_2$;
X = total reactance in terms of primary;
I_M = primary magnetizing current;
$I_H = \dfrac{\text{core-loss}}{uE_2}$, to a close approximation;
E_1 = primary impressed e.m.f.;
I_1 = total primary current;
$\cos\theta_1$ = power factor of transformer with load, i.e., power factor at primary terminals;
P_1 = watts input at primary terminals;
η = per cent efficiency.

Then

$$E_1 = \sqrt{(E_2'\cos\theta_2 + RI_1)^2 + (E_2'\sin\theta_2 + XI_1)^2};$$
$$I_1 = \sqrt{(I_2'\cos\theta_2 + I_H)^2 + (I_2'\sin\theta_2 + I_M)^2};$$
$$P_1 = E_2 I_2 \cos\theta_2 + R(I_2')^2 + E_2' I_H;$$
$$\cos\theta_1 = \frac{P_1}{E_1 I_1};$$
$$\eta = \frac{100\,P_2}{P_1};$$
$$P_2 = E_2 I_2 \cos\theta_2;$$
$$\text{Per cent regulation} = \frac{100\,(E_1 - uE_2)}{uE_2}.$$

Constant-current Transformers are used for supplying current to arc lamps connected in a series circuit which requires from 4 to 10 amperes and about 2000 volts. The principle of operation for this type of transformer is based on the existence of the leakage or useless flux which causes a repelling force between the primary and secondary windings. One winding is arranged so that it may move with respect to the other. As the current in the windings increases the repelling force increases and the windings move apart. This allows more flux to leak or pass between the windings and less to thread the secondary. Therefore the voltage induced in the secondary decreases as the current tends to increase. A counterweight is attached to the movable winding to regulate the amount of movement. The current in the primary remains fairly constant, but the power factor decreases with decreasing load on the secondary so the power in the primary is approximately proportional to the output of the secondary.

Series Transformers operate under conditions similar to those in a constant-potential transformer with short-circuited secondary. Under operating conditions the flux is small as the only voltage to be induced in the secondary is that required to overcome the impedance drop in that winding and the instrument which it supplies. The only counter e.m.f. in the primary is that due to impedance drop. The series transformer must be operated with the secondary

short circuited by a low impedance. If the secondary circuit is open there is no counter m.m.f. to balance the primary turns, which, being in series with the main line, carry a current irrespective of the secondary circuit. The primary ampere-turns would then set up a magnetic flux of considerable magnitude. As the transformer is not designed for this condition, the density would become very high in the magnetic circuit of small cross-section, and the transformer is liable to burn up from the heat due to core-loss.

TRANSFORMER CONNECTIONS. — The various transformer connections which are commonly used in lighting and power services are described below; see also section on *Operation* below.

Single-phase System with Three-wire Secondary (Fig. 9). — Standard practice in residence lighting with the a-c. system involves grounding the neutral wire on the low-tension side, the primary side not being grounded. Lamps or motors operating at 110 volts are connected between the neutral and either

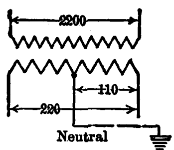

Fig. 9. Single-phase, Three-wire

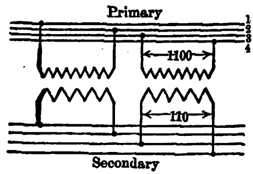

Fig. 10. Two-phase, Four-wire

side. The maximum potential between any secondary and ground is 110 volts but if either of the outside wires becomes grounded it constitutes a short-circuit on that half of the transformer.

Two-phase or Quarter-phase Four-wire System (Fig. 10).—The standard two-phase or quarter-phase system is essentially two independent single-phase systems which are usually independent electrically throughout. When the two phases are not electrically connected inside the generator, either wire of one phase may be connected to either wire of the other phase, without any flow of current resulting. In certain two-phase generators, however, the windings are interconnected, in which case any interconnection of the wires coming from the generator will cause a flow of current through this connection.

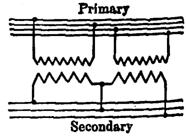

Fig. 11. Two-phase, Three-wire

Two-phase Three-wire System (Fig. 11). — This connection is occasionally used for the distribution of power in small systems. There is a possibility of a slight saving in copper, but the chances of unbalanced voltage and bad regulation, particularly with an inductive load, render it objectionable.

Three-phase Y and Δ Connections (Figs. 12 and 13). — Transformation in a three-phase system with either three independent single-phase transformers or with a three-phase transformer, having three primary coils and three secondary coils on one iron core, is accomplished by connecting the primary either in Y or in Δ and the secondary either in Y or in Δ. With Y or Δ connections there are the following relations between voltage per transformer winding and voltage between lines, and between current in transformer windings and current in lines. The power in the three transformers in any case is $3 \times 0.58 \times EI = 1.73\ EI$,

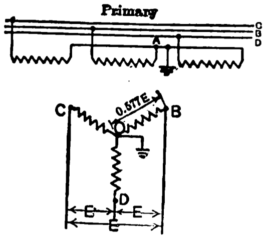

Fig. 12. Three-phase Y

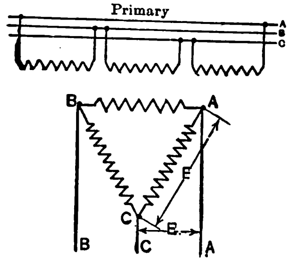

Fig. 13. Three-phase Delta

Connection	Volts bet. lines	Volts per winding	Current per line	Current per winding
Y	E	0.58 E	I	I
Δ	E	E	I	0.58 I

There are four combinations of these connections which may be used on any bank of transformers. These connections are given in the following table, and also the ratio of the voltage between lines for the low-tension and high-tension sides for a given ratio (u) of transformation in each individual transformer connection.

Connection		Low-potential volts bet. lines	High-potential volts bet. lines
Low pot.	High pot.		
Δ	Δ	E	uE
Y	Y	E	uE
Δ	Y	E	1.73 uE
Y	Δ	E	0.58 uE

Parallel Connection of Three-Phase Banks. — If there are several banks of transformers in the same system connected in parallel on one side then to connect the other sides in parallel the connections must be such that the voltage between any two lines on this side will have the same phase in all the banks. From this relation result the following rules:

With $\Delta\Delta$ on one bank, the other bank must be $\Delta\Delta$ or YY.
With YY on one bank, the other bank must be $\Delta\Delta$ or YY.
With ΔY on one bank, the other bank must be ΔY or $Y\Delta$.
With $Y\Delta$ on one bank, the other bank must be $Y\Delta$ or ΔY.

Even when these relations are satisfied a short-circuit will result unless the three phases of each bank are connected in the proper sequence. This can be

readily determined by the polarity test described below in the section on *Testing.*

Relative Advantages of Y and Δ Connections. — There has been much discussion as to the relative advantages of *Y*- and Δ-connected transformers for high-tension transmission and as to the value of a grounded neutral. The general and fundamental arguments may be summed up as follows:

With a ΔΔ-system the advantages are that if one transformer becomes disabled the system may be operated from the other two, operating on open delta (*see below*). If the load is unbalanced the voltages do not become unduly unbalanced. Resonance cannot occur. On the other hand, each transformer must be insulated for full line voltage as there is no neutral to ground, and if one line becomes grounded the voltage strain on the rest of the system becomes 1.73 times the normal strain, and this strain may extend to the low-tension winding and the generator which is connected to the transformers.

With a *YY*-connection there is a very unstable neutral and a possible excessive voltage strain on one phase, unless the neutral is grounded.

With a Δ*Y* arrangement for step-up transformers, the neutral on the high-tension side may be grounded. The voltage strain on any transformer is then limited to 58 per cent of the line voltage. There is a possibility of operating the remaining two transformers, if one becomes damaged, by using the neutral as a third conductor. However, there is the possibility of resonance under certain circumstances and the danger of causing disturbances in nearby telephone and telegraph circuits. Any accidental ground on the system makes a definite short-circuit on one phase.

The arrangement of *Y*Δ for step-up transformers is not desirable on account of the unstable neutral with unbalanced load, but is permissible with a balanced load or with a good connection from neutral of transformers to neutral of generator. This connection, however, is frequently used for step-down transformers particularly when connected to a balanced load.

Grounded Neutral vs. Ungrounded Neutral. — In any system without a grounded neutral there are numerous possibilities of disturbances resulting in a high voltage strain on the various parts of the insulation of the system. With the high voltages now in use for transmission systems these disturbances may give a great deal of trouble by breaking down the insulation, as it is not always possible to employ a large margin of safety and lightning arresters do not always protect from these disturbances. On the other hand, if the neutral is grounded, most of these disturbances will merely result in an excessive current, and if the circuit breakers are installed in the proper places they will open the circuit, so that the only adverse result will be a temporary interruption of service.

The choice is then between a system with ungrounded neutral and a large margin of safety in the insulation, and a system with grounded neutral, moderate insulation and the possibility of occasional interruption of service.

Effect of Higher Harmonics. — Many alternators generate an e.m.f. whose wave shape contains higher harmonics (*see Wave Analysis*) and the magnetizing current of transformers operating at high magnetic densities has a distorted wave shape which contains a prominent third harmonic. If these harmonics are present in a *Y*-connected machine they cause the voltage between each line and the neutral to vary so that there exists an unstable neutral, and the voltage strain on any one phase is indeterminate. If the neutrals of two pieces of apparatus in which these harmonics exist are grounded or joined together, a high-frequency current will flow in the neutral connection. If on the other hand these pieces of apparatus are Δ-connected a third harmonic current will circulate inside the apparatus. This may be measured by con-

necting an ammeter in the Δ between two phases. This current heats the apparatus, does no profitable work, and is therefore to be avoided. High frequency current in the line will cause high voltages to occur at certain points if a large amount of capacity is present, as is the case in any underground line, even of moderate length, and also in long overhead lines. All possible means both in the design of the generators and the connection of the apparatus should be taken to prevent the occurrence of, or to diminish the effect of, these higher harmonics.

Three-phase Open Δ or V Connection (Fig. 14). — This system consists in omitting one transformer from the delta connection, and is used to save expense, particularly in temporary installations or in new installations where the load is not great at first but is expected to increase in time. Thus the

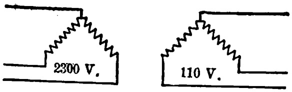

Fig. 14. Three-phase, Open Delta

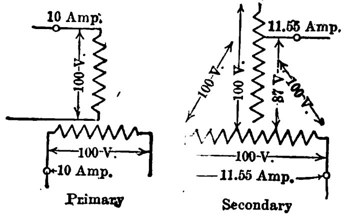

Fig. 15. Two-phase to Three-phase

purchase and installation of the third transformer is postponed until the load requires it. This connection can only be recommended for low voltages, such as 2300, as it is liable to produce dangerous potentials due to electrostatic unbalancing. The regulation and efficiency are also poor, as one phase of the load receives its power from two transformers in series. The aggregate capacity of the two transformers should be 15 per cent greater than the load.

Two-phase to Three-phase Transformation (Fig. 15). — The Scott or *T*-connection, the standard method of transforming from two-phase to three-phase, consists of two transformers which on the two-phase side may be connected in the normal two-phase manner either independently or interlinked. On the three-phase side one transformer has a tap at the middle point and the other a tap giving 87 per cent of full-transformer voltage. Fig. 15 shows the method of connecting and the currents in primary and secondary with balanced loads. Since the total power is $2 E_2 I_2 = \sqrt{3} E_3 I_3$, it follows that $I_3 = \frac{2}{\sqrt{3}} \frac{E_2}{E_3} I_2$, or the three-phase current is 16 per cent greater than it would be for straight single- or two-phase transformation. Thus the total transformer capacity must be 4 per cent greater than the load.

In commercial practice it is customary for the sake of interchangeability to make the capacity of both transformers 16 per cent greater than the load and to put both a 50 per cent and 87 per cent tap on both transformers. For this connection of transformers each half of the main transformer winding must be distributed over both legs of the core in order to prevent flux (and therefore voltage) unbalancing. If this precaution is taken both the primary and secondary voltages are balanced if the load is balanced. Any unbalancing of the secondary causes a like amount of unbalancing on the primary; thus if this connection is used to transform from 3-phase to 2-phase and all the load comes on one phase of the secondary it will also come on one phase of the primary.

Transformer Connection for Synchronous Converters.—For a two-phase converter the connections are simple as shown under *Converters*. For a three-phase converter there is a choice between Δ or *Y* secondaries, which is usually decided in deference to the conditions in the high-tension line. The delta connection is customary in railway substations. A diagram of the connections is given in the article on *Converters, Synchronous*. When the converter is to supply a three-wire d-c. lighting system, the "distributed" *Y* connection for the secondary should be used as shown in Fig. 16. By this arrangement the unbalanced current from the d-c. neutral is divided, and sent through the two halves of each transformer in opposite directions. Thus it does not increase the magnetic densities in the transformers, and avoids the excessive core-loss which would occur with a simple *Y* connection.

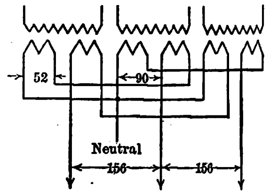

Fig. 16. Distributed Y for Three-wire Converter

For six-phase converters there is the choice between the "diametrical" and "double delta" connections as shown in Figs. 17 and 18. The diametrical is common with railway converters, or where the conditions are such that the delta is not needed to prevent an unstable neutral.

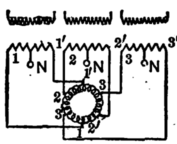

Fig. 17. Six-phase Diametrical

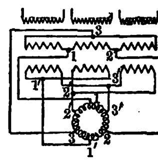

Fig. 18. Six-phase Delta

For regulating pole or split-pole converters certain special conditions must be borne in mind in choosing between the diametrical and the double-Δ connections. With the variation of the direct voltage of the converter the wave shape of the alternating e.m.f. is distorted and this introduces harmonics in either the counter e.m.f. or current waves, among which the third is quite prominent. If the delta connection is used a local harmonic current circulates in the converter armature and transformer secondaries, which increases the losses and heating and lowers the efficiency. If the diametrical connection is used the higher harmonic voltage gives an unstable neutral, and introduces extra potential strains in the high-tension windings and line if *Y*-connected. This may be obviated by grounding the neutral, but then a considerable current may flow in the neutral connection, which may interfere with neighboring circuits. The best solution is to use the diametrical connection in the secondary and ungrounded *Y* in primary, and use transformers having a good margin of safety in the insulation of the high-tension side.

THREE-PHASE TRANSFORMERS. — Considerable space, wiring and first cost may be saved by the use of a three-phase transformer in place of three single-phase transformers. This saving is warranted in large installations, but not in small installations where the convenience of having one interchangeable single-phase transformer as a spare for several banks of three transformers each is an important item.

Core of Three-Phase Transformer. — Three-phase transformers may be of the core type as shown in Fig. 1, in which case all the magnetic paths are of the same cross-section, or of the shell type shown in Fig. 2. In the latter type the horizontal cross pieces and outside vertical pieces may have one-half the cross-section of the central vertical core, providing the coil on the central leg is connected with a definite polarity with respect to the other two coils in order to have the fluxes differ in phase by 60 degrees.

Operation of Damaged Three-phase Transformer. — In a shell-type three-phase transformer if the primary and secondary are delta-connected it is possible to operate with only two phases in open delta at reduced capacity in case of trouble in the third phase of the system. This is accomplished by separating the third phase entirely from the system and short-circuiting both the primary and secondary windings.

DESIGN. — (*See also section below on Cooling of Transformers.*) The methods of design for single-phase and polyphase transformers are similar, the chief difference being that of the magnetic circuit. In the design of polyphase transformers each leg is treated as an independent single-phase transformer. The number of turns is adjusted to the voltage per phase and the cross-section of the conductors to the current per phase. All legs are wound alike and the phases are connected up as described in the preceding section.

The alternating-current transformer is the most efficient piece of electric apparatus. Its efficiency at full load is usually better than 95 per cent and frequently better than 98 per cent. For this reason it is very small in volume and light in weight for a given output compared to other pieces of electrical apparatus and hence the chief difficulty in design is the necessity of providing sufficient surface and a proper means to carry off the heat developed.

The difference in mechanical construction between the core and shell type is that the winding of the core type usually consists of two or more long spools (in which the length is considerably greater than the diameter) surrounding each leg of the transformer. The shell type consists usually of large flat "pan-cake" coils, laid alongside of each other on the central core with proper separating devices to permit ventilation. See Figs. 1 and 2.

The following discussion applies alike to both core and shell types except where specific mention to one or the other is made.

Preliminary Calculation of Main Dimensions. — **Let**

E_1 = primary voltage, effective value;
I_1 = primary full-load current, effective value;
E_2 = secondary voltage, effective value;
I_2 = secondary full-load current, effective value;
f = frequency in cycles per second;
S_1 = number of primary turns;
S_2 = number of secondary turns;
ϕ = maximum value of flux;
$C = \dfrac{\phi}{S_1 I_1}$ = ratio of total flux to full-load primary ampere-turns;
e = volts per turn, effective value;
B = maximum value of magnetic flux density in lines per square inch;
A = cross-section of core in square inches;
f_1 = space factor of winding space;
D = total section of copper in square inches;
U = current density in amperes per square inch;
σ = ampere-conductors per inch length of core.

Determination of Flux (ϕ) and Number of Primary Turns (S_1).—In order to estimate a desirable value of the flux to be used there is employed a factor C which is defined by the relation

$$C = \frac{\phi}{S_1 I_1}. \qquad (1)$$

The proper value of this factor C depends upon the type, capacity and voltage of the transformer, and the relative weights of copper and iron.* Usual values are given in the accompanying table.

VALUES OF C

Form of transformer	Voltage	Core type	Shell type
		Value of C	Value of C
Natural draft	0–6000	55–70	500–700
	6000 up	70–75	500–700
Oil-cooled	0–10,000	75–100	
	10,000 up	100–150	
Air-blast or water-cooled	0–10,000	110–160	600–1000
	10,000 up	160–240	600–1000

The relation between the effective value of the primary voltage and the maximum value of the flux is

$$E_1 = 4.44 f S_1 \phi \times 10^{-8}. \qquad (2)$$

Inserting in equations (1) and (2) the proper values of the primary voltage E_1, the frequency f, the constant C and the primary full-load current I_1, and solving the two equations for ϕ and S_1, reasonable values for the flux ϕ and the number of primary turns S_1 are obtained.

In the preliminary estimation of the full-load primary current I_1 it is sufficiently accurate to ignore the efficiency and power factor and to take the current as the watts output divided by primary voltage.

Volts per Turn (e).—The above value of ϕ should be checked by finding the volts per turn,

$$e = 4.44 f \phi \times 10^{-8},$$

and comparing it with values used in practice. In large transformers a greater voltage between turns is permissible than in small transformers. The accompanying table for core-type transformers is based on the assumption that double-cotton-covered wire is used for the windings. With special insulation higher values may be used.

Kilowatt rating of transformer	Allowable volts per turn for core type
10	2.5
20	3.5
50	5.5
100	7
200	9
500	13
1000	18

Number of Secondary Turns (S_2).—Having determined in a preliminary way the number of primary turns, the number of turns in the secondary is $S_2 = \frac{E_2}{E_1} S_1$. It will considerably simplify the mechanical arrangement of the coils if S_2 is divisible by 4. The nearest multiple of 4 is taken as the final value of S_2 and then S_1 and ϕ are readjusted to correspond to this value of S_2.

* A discussion of this factor C will be found in Arnold's *Transformers* and in S. P. Thompson's *Dynamo Electric Machinery*, Vol. II.

Cross-section of Core (A) **and Magnetic Flux Density** (B). — The core section is determined by the magnetic density which it is desirable to use, which in turn is determined by the core-loss. It is found that in average practice a loss of one watt per pound of iron can be dissipated without excessive rise in temperature. The corresponding flux densities in iron having a thickness of 14 mils are given in the following table. These values are approximate only, since the quality of the steel used is exceedingly variable. It should also be noted for a transformer intended for supplying a load of low power factor that the iron loss should be less than 1 watt per pound for the best distribution of material.

VALUES OF FLUX DENSITY

Size of transformer	Kind of steel	Lines per sq. in.	
		25 cycles	60 cycles
Small	Ordinary transformer sheet	50,000	40,000
Small	Special; silicon-steel	70,000	60,000
Large	Ordinary transformer sheet	75,000	65,000
Large	Special; silicon-steel	90,000	75,000

The proper cross-section of core in square inches is then

$$A = \frac{\phi}{B}.$$

In the core type this cross-section may be assumed as a square whose side is d. Since the core is made up of laminations whose effective length one way is 0.9 d, the value of d is

$$d = \sqrt{\frac{A}{0.9}}.$$

In the shell type this cross-section is a rectangle whose length is from 2 to 3 times its width.

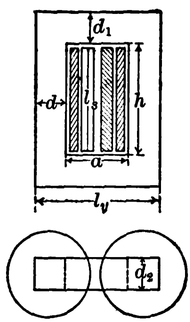

Fig. 19. Dimensions, Core Type

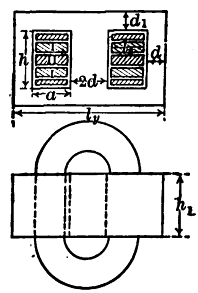

Fig. 20. Dimensions, Shell Type

Dimensions of Winding Space (Figs. 19 and 20). — The area or cross-section of the "window" or winding space depends upon the amount of copper,

insulation and ventilating space. The first can be determined accurately by the chosen current density in the copper. The second and third are allowed for by a space factor (f_1) which gives the ratio of the actual total cross-section of copper (D) to the cross-section of the window. Usual values of f_1 are given in the following table.

SPACE FACTOR IN TRANSFORMERS (f_1)

Size of transformer, Kw.	Core type		Shell type		
	Up to 10,000 volts	33,000 volts	Up to 2000 volts	2000 to 10,000 volts	33,000 volts
0–50	0.22	0.15	....	....	....
50–1000	0.33	0.25	0.40	0.33	0.18
Above 1000	0.38	0.33	0.45	0.36	0.21

In the core type there is one window and it contains $S_1I_1 + S_2I_2$ ampere conductors; in the shell type there are two windows and each contains $S_1I_1 + S_2I_2$ ampere conductors. The cross-section of copper in one window in either case is

$$D = \frac{S_1I_1 + S_2I_2}{U} = \frac{2\,S_1I_1}{U},$$

where U, the current density in amperes per square inch, has the following values:

Condition of transformer	U = amperes per sq. in.
Poorly cooled	850–1200
Ordinary oil cooled, air blast, etc.	1100–1600
Large, well cooled	1500–1900

Then the height h and width a of the window, see Figs. 19 and 20, must be such that

$$ha = \frac{D}{f_1}.$$

Height of Core. — In the core type this depends upon the ampere-turns or ampere-conductors per inch length of core, which in turn is related to the heating. The ampere-conductors per inch length of core is

$$\sigma = \frac{S_1I_1 + S_2I_2}{2\,h} = \frac{S_1I_1}{h},$$

where h is the height of core.

For a maximum rise in temperature of 50° C. σ will have values as given in the accompanying table. A reasonable value of h can then be found.

Form of transformer	σ = amp. conductors per inch of core
Natural cooled	500–750
Oil cooled or air blast	750–1250
Water cooled	1250–2000

In the shell-type transformer the practice is to make the height (h) from 1.5 to 3 times the width of window (a) and the width of window from 0.75 to 1.25 times the width of the central iron core, $2d$ in Fig. 20. See also paragraph above on *Cross-section of Core.*

Details of the Winding. —

$$\text{Cross-section of primary conductor in square inches} = \frac{I_1}{U}.$$

$$\text{Cross-section of secondary conductor in square inches} = \frac{I_2}{U}.$$

For minimum loss the copper density should be the same in both members, but to save space the copper density in the high-potential winding is sometimes greater than that in the low-potential winding.

The low-potential winding is usually placed between the high-potential winding and the iron.

Each coil is now laid out in detail, placing as many turns in a layer as the height and insulation will allow. The voltage per layer must not exceed 150 to 200 volts. A space of 10 mils is to be allowed for insulation between layers when insulated wire is used and 8 mils when insulated strip is used. The space between coils is from 0.04 to 0.30 inch, depending upon the voltage per coil. Space for the air or oil ducts is also provided. Each duct is from ⅛ to ⅜ inch wide and there should be one on each side of each coil. No part of the winding should be more than ⅜ inch from the surface of a duct.

Insulation of Windings.— The insulation of each turn usually consists of the cotton covering if the coils are wound with wire, or mica paper if the coils are wound with strip copper. This is proportioned to withstand the potential between turns as given above. The voltage between conductors on adjacent layers may be equal to twice the voltage per layer. To prevent breaking down between layers, a layer of Fuller board is used as a separator and this should project beyond the windings at the ends to prevent creepage. The maximum voltage between layers should be kept below 400 and to accomplish this it is customary to limit the voltage per coil to about 5000 volts. Between the windings and the core a layer of pressboard and sometimes wood is placed, while between primary and secondary windings a layer of pressboard and micanite may be used. For very high voltages the end turns of the high-tension winding for about 75 feet from the terminals is given a special insulation to withstand the sudden high potentials which occur when there is a sudden change in the potential applied to the transformer. These high potentials result from the distributed capacity of the transformer, between the high-tension winding and the core, frame and other winding.

Terminal Bushings. — At the point where the high potential leads pass through the case there is a very great dielectric stress which must be taken care of by the use of a proper kind of insulation and a proper disposition of the

insulation to prevent a concentration of the dielectric flux at a few points. For voltages below 40,000 a porcelain bushing is customarily used.

For higher voltages it is necessary to supply a large creepage distance and to have the surface submerged in oil to prevent corona effect. This is accomplished in one form of bushing, known as the "condenser type," by surrounding the terminal with layers of insulation and putting sheets of tinfoil between the layers. This arrangement is equivalent to a series of condensers. By properly proportioning the area of the successive layers of tinfoil the drop in potential across the insulation is kept uniform. The whole terminal is inclosed in an oil-filled casing. Another form of bushing known as the "oil-filled type" consists of a long cylinder of composition insulation which surrounds the lead and is filled with oil. The cylinder is divided into compartments to keep the oil properly distributed, and disks or collars project outward from the outside to increase the creepage distance.

End Coils of Shell Type. — With the flat coils customarily used in the shell-type transformer the subdivision of the windings is usually such that there is a half coil of the low-potential winding at each end of the winding space as in Fig. 20. This is to reduce the leakage flux. In order to further reduce the leakage flux all coils may be divided into halves with a ventilating duct between halves. The space between a primary and secondary coil is then reduced to that necessary for the insulation.

Adjustment of Core Dimensions. — After the final details of the windings are arranged the cross-section and length of core is finally settled. Sometimes the cross-section of core in the core type is made cruciform instead of square in order to use more effectively the area inside of circular coils.

PREDETERMINATION OF THE PERFORMANCE OF A TRANSFORMER. — From the above calculations a drawing to scale of the transformer may be laid out. The next step is to calculate its performance, i.e., to predetermine the values of the efficiency, regulation and temperature rise. This last feature is treated in the following section on the *Cooling of Transformers*.

Magnetizing Current (I_M). — The final flux density will probably differ a few per cent from the value assumed earlier in the calculation. The cross-section of core is usually proportioned to give the same magnetic density in all parts, as this condition gives minimum core-loss for a given weight of iron.

The mean length of path in the iron is measured or calculated. If H (found from the magnetization curve of the iron, see article on *Magnetic Properties of Iron*) is the ampere-turns per inch for the given density the magnetizing current of the transformer will be

$$I_M = \frac{H \times (\text{length path})}{\sqrt{2}\, S_1}.$$

Sometimes it is desired to allow for the minute air gaps at the joints of the punchings. Arnold finds that under practical conditions each joint represents a gap of 0.002 inch. Thus if there are n joints (usually 4) there should be added to I_M an amount

$$\frac{0.313 \times 0.002\, Bn}{\sqrt{2}\, S_1}.$$

Core-loss. — The core-loss consists of hysteresis and eddy losses in the steel punchings. These losses have been considerably reduced in recent years

by improvements in the manufacture and quality of the steel (*see article on Magnetic Properties of Iron*).

$$\text{Core-loss} = k_1 f V \left(\frac{B}{1000}\right)^{1.6} 10^{-6} + k_2 V \left(t f \frac{B}{1000}\right)^{2} 10^{-5} \text{ watts,}$$

where f = frequency in cycles per second;
V = volume of iron in cubic inches;
B = magnetic density in lines per square inch;
t = thickness of laminations in inches;
k_1 = a constant, ranging from 8 in ordinary transformer steel to 4 in silicon-steel;
k_2 = a constant, ranging from 4 in ordinary transformer steel to 1.5 in silicon-steel.

The core-loss may be calculated more easily by the method and curves given in the article on *Magnetic Properties of Iron*.

Copper Loss. — The mean length of turn of both primary and secondary windings is obtained from a sketch to scale. The direct-current or ohmic resistance of each member at 60° C. is obtained by substituting the proper values in the formula

$$R = \frac{0.0093\, lS}{12{,}000\, an},$$

where l = mean length of turn of primary or secondary respectively in inches,
S = number of turns in series,
a = cross-section of conductor in square inches,
n = number of conductors or coils in multiple.

To allow for eddy currents caused by the leakage flux, the above resistance is increased by 15 per cent to give the effective resistances r_1 and r_2. The total copper loss is then $I_1^2 r_1 + I_2^2 r_2$.

Transformer Reactance. — As explained in the section above on *Transformer Principles*, the leakage of flux between the primary and secondary windings of a transformer causes a component of voltage in each member which is out of phase with the current; if the current lags very much this voltage may have a considerable component opposed to the useful voltage and cause a loss of voltage or poor regulation. It is, therefore, necessary in designing to estimate the amount of this flux and calculate the voltage it would produce. In practice empirical formulæ are usually used, but a logically deduced formula is desirable as it is more easily adapted to unusual cases.

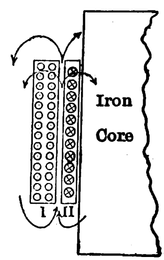

Fig. 21. Leakage Flux

The phase of the current in the secondary coil is nearly opposed to that in the primary and may be assumed to be exactly opposed without any great error. The result as shown in Fig. 21 is that all these ampere-conductors, both primary and secondary, tend to set up a flux in the same direction in the space between the windings and to a lesser degree in the windings themselves. A part of the flux in the intervening space interlinks with the primary turns and another part with the secondary turns. In addition the flux in the windings themselves interlinks with some of the turns. The flux in each part is proportional to the ampere turns producing it and to the permeance of the path. In this case since the path is in air, the permeance is the area divided by the length, where the length is the average length of the flux lines.

The leakage flux passes between the windings and one part closes its path in the iron inside the inner coil and the other part in air outside the outer coil (in the core type). The reluctance of the path between the two coils is large compared to that of the other two portions, because the inside path has a high permeability and the outside path has a large cross-section. The reluctance of the path between the coils is therefore accurately (and easily) calculated and a constant used to allow for the rest of the path.

In order to calculate the inductance it is necessary to have a cross-section of the windings showing their thickness, length and arrangement, as in Figs. 19 and 20.

Two cases must be considered:

(A) Where there are as many primary coils as secondary coils, and all coils are full size (usual core type).

(B) Where there is a "half" secondary coil at each extremity of the group of windings (the usual arrangement in the shell-type transformers).

Arnold's Method of Calculating Reactance. — Arnold calculates the inductance of a single primary coil and its secondary mate or mates, and multiplies this by the number of primary coils in series or divides by the number in multiple. This gives the total "short-circuit" inductance of the transformer in terms of the primary voltage or turns.

Referring to Figs. 19 and 20 for the core and the shell type respectively, let the various quantities be represented as follows, all dimensions being in inches:

q = number of primary coils in series,
p = number of primary coils in parallel,
s_1 = number of turns in one primary coil,
s_2 = number of turns in one whole secondary coil,
l_s = height of coils in cylinder type,
l_s = depth of coils in flat type,
t_1 = thickness of a whole primary coil,
t_2 = thickness of a whole secondary coil,
t = distance between coils,
U_1 and U_2 = mean length of primary and secondary turns respectively,
U_m = average of U_1 and U_2,
k = an empirical constant, varying from 0.95 with flat coils to 1.06 with cylinder coils.

Reactance of Core Type (Fig. 19). — In a core-type transformer with cylindrical coils and an equal number of full-sized primary and secondary coils, the permeance of the path of the flux in the duct which interlinks with a primary coil is $\frac{tU_1}{2\,l_s}$ and the permeance of the path in the winding itself is $\frac{t_1U_1}{3\,l_s}$.

The inductance of one primary coil is

$$L_1 = \frac{3.2\,ks_1^2U_1}{l_s}\left(\frac{t_1}{3}+\frac{t}{2}\right)10^{-8}.$$

The inductance of one secondary coil is

$$L_2 = \frac{3.2\,ks_2^2U_2}{l_s}\left(\frac{t_2}{3}+\frac{t}{2}\right)10^{-8}.$$

Reducing the latter to terms of the primary turns by multiplying by $\frac{s_1^2}{s_2^2}$, adding together and multiplying by $2\pi f$, the total reactance of the transformer in terms of the primary is

$$X = 2\pi f\,\frac{3.2\,qks_1^2U_m}{pl_s}\left(\frac{t_1+t_2}{3}+t\right)10^{-8}.$$

Reactance of Shell Type. — If, as in the shell-type transformer shown in Fig. 20, there is a half secondary coil at each end to give an increased intermixing, then

$$X = 2\pi f \frac{3.2\, qks_1^2 U_m}{2\, pl_s} \left(\frac{l_1 + l_2}{6} + t \right) 10^{-8}.$$

Efficiency and Regulation. — The efficiency and regulation may be calculated as described above under *"Equivalent" Circuit of Transformer*, p. 1610, or by the following method, which is sufficiently accurate for most practical purposes.

Let

E_2 = secondary terminal voltage,
I_2 = secondary current,
$\cos\theta_2$ = power factor of load on secondary,
$P_2 = E_2 I_2 \cos\theta_2$ = secondary output in watts,
A = core-loss in watts = input for no load on secondary, approximately,
u = ratio of number of primary to number of secondary turns,
$R_2 = \dfrac{r_1}{u^2} + r_2$ = total resistance in terms of secondary, r_1 and r_2 being the actual resistances of primary and secondary respectively,
$X_2 = \dfrac{X}{u^2}$ = total reactance in terms of secondary, where X is the total reactance in terms of primary.

Then the per cent efficiency is

$$\eta = \frac{100\, P_2}{P_2 + A + R_2 I_2^2}.$$

Secondary voltage at no load is

$$E_{20} = \sqrt{(E_2 \cos\theta_2 + R_2 I_2)^2 + (E_2 \sin\theta_2 + X_2 I_2)^2}$$

and the regulation is then

$$\frac{100\,(E_{20} - E_2)}{E_2} \text{ per cent.}$$

All-day Efficiency. — The all-day efficiency is the ratio that would exist between the readings of a watt-hour meter connected on the secondary and a similar meter on the primary. It is of importance because a great many transformers, particularly for lighting, operate at full load for only a few hours each day, but the core-loss or iron losses are just as great when the load is very light or when there is no load at all. Hence these transformers may waste a great deal of energy, although their efficiency at full load is very good.

To calculate the all-day efficiency multiply each quantity in the usual formula for efficiency by the number of hours per day that this factor occurs; thus

$$\text{All-day eff.} = \frac{100\, P_2 \times h}{P_2 \times h + h_1 A + h R_2 I_2^2} \text{ per cent,}$$

where h = hours per day of secondary load; h_1 = hours per day that transformer is on line, and the other symbols as above. Since the core-loss occurs 24 hours a day and P_2 only 2 or 3 hours, the importance of making the core-loss low in a transformer for this class of service is apparent.

However, there is another side to the question, since energy may not be worth as much during the day when there is little demand on the central station, as in the evening when the demand is great.

EXAMPLES OF DESIGN. — In the following table are given the chief design characteristics of four different transformers.

EXAMPLES OF SINGLE-PHASE TRANSFORMER DESIGN

American or foreign	Foreign	Foreign	American	American
Form (cooling)	Oil	Air	Oil	Air
Type	Core	Shell	Distributed	Shell
Frequency	50	50	60	25
Kv-a. rating	40	100	20	75
High-tension voltage	3120	2200	2200	2500
Low-tension voltage	230	110	220	320
C (design constant)	56	670	222	1550
High-tension Winding:				
Current at rating, amperes	12.8	45.5	9.1	30
Total turns in series	1408	180	640	219
Coils in series	8	4	2	3
Coils in multiple	1	1	1	1
Size of conductor, inches	$d = 0.183$	0.79×0.059	0.105×0.09	0.34×0.08
Resistance at 25° C., ohms	1.13	0.24	1.43	0.492
Low-tension Winding:				
Total turns in series	104	9	64	28
Coils in series	4	1	4	4
Coils in multiple	1	3	1	1
Size of conductor, inches	0.59×0.13	0.87×0.1	2, each 0.23×0.155	6, each 0.34×0.09
Resistance at 25° C., ohms	0.009	0.00059	0.0204	0.0095
Flux density in core, kilolines per square inch	38.6	52	68	67.5
Core dimens., inches, length	(26 sq. in.)	5.1	4.6	8
Core dimens., inches, width	......	22.8	4.6	21
Window dimens., inches, height	35.5	5.9	9.2	5.5
Window dimens., inches, width	5.45	9.9	3.1	8
Magnetizing current, amperes	0.21	2.12	0.432	1.82
Core-loss, watts	490	1320	164	1520
No-load current, per cent	2.04	4.85	4.8	6.9
Core-loss, per cent	1.22	1.30	0.80	1.96
Primary, RI^2, per cent	0.50	0.52	0.59	0.57
Secondary, RI^2, per cent	0.68	0.48	0.81	0.67
Efficiency, per cent	97.6	97.7	97.8	96.8
Total XI drop, per cent	1	2	2.84	1.36

COOLING OF TRANSFORMERS. — It is necessary to keep the temperature of the various parts of a transformer within such limits that the materials of which it is constructed do not become damaged and deteriorate too rapidly. When subjected to too high a temperature the insulating materials disintegrate and lose their mechanical and dielectric strength, and the iron deteriorates in its magnetic qualities so that the core-loss becomes greater for a given density. This so-called ageing of the iron may cause an increase of as much as 50 per cent in the loss in the iron. The effect varies with the character of the iron and is practically negligible in silicon-steel.

Maximum Rise in Temperature.—The maximum rise in temperature above a room temperature of 25° C. at which the various materials of a transformer should be operated are given in the table.

Material	°C
Iron..................	70–75
Cotton................	60
Paper.................	70
Mica, asbestos.........	90

To guard against this possibility of damage the Standardization Rules of the A.I.E.E. recommend that the windings shall not increase in temperature more than 50° C., as measured by resistance, above the surrounding air, and the other parts shall not increase more than 50° C. as measured by thermometer.

Means of Dissipating Heat. — The problem is to provide a path of low thermal resistance by which the heat energy may pass to the surrounding air. To accomplish this it is necessary, first, to provide sufficient surface in the subdivided transformer to transfer the heat to the cooling agent, air or oil, without too great a difference in temperature; second, to so subdivide the transformer that no part of the iron is more than one inch, and no part of the copper more than ⅜ inch, from a cooling surface; third, to provide a sufficient quantity of the cooling agent, air, oil or water to carry away the heat at the same rate as it is generated; and fourth, to provide sufficient surface on the containing case or tank to transfer the heat from the internal oil to the external air without too great a difference in temperature.

Calculation of Exposed Surface of Transformer.— The practical method of estimating the rise in temperature consists in calculating the drop in temperature in the successive media by finding the watts to be dissipated per square inch of each surface. The first step is to calculate the exposed surface.

The total exposed surface (A_t) of the transformer proper, that is, the surface in contact with the cooling medium, is to be calculated. For core-type transformer, dimensions in inches and symbols as in Fig. 19:

$$A_t = (\text{number of cores}) \times [(\text{outer perimeter of windings})\, l_s + 2\,(\text{end surface of windings}) + h\,(\text{perimeter of core}) + (\text{number of ducts in core}) \times (\text{surface of one duct})] + (2 + \text{number of ducts in yoke}) \times l_y d_1 + 2\,(l_y d_2 + 2 d_1 d_2).$$

For shell-type transformer, dimensions in inches and symbols as in Fig. 20:

$$A_t = d\,[2\,(2\,a + 4\,d) + 2\,h]\,(2 + \text{number of ducts}) + h_1\,[2\,(2\,a + 6\,d) + 2\,\text{h}] + [2\,l_s h_1 + \pi\,(2d + a)\,l_s]\,(2 + \text{number of ducts in windings}).$$

In the preceding formulæ only half the duct surface is used, as with narrow ducts these surfaces are only half as effective as outside surfaces. If the ducts have a width of one inch then the whole surface may be used.

Naturally-cooled Transformers should have from 4.75 to 5.3 square inches of surface (A_t) for each watt loss for 50° C. rise in temperature.

Oil-cooled Transformers. — (*See also Oil, Transformer.*) The transformer is submerged in oil in a tank so that the level of the oil is from 2 to 3 inches above the top of the transformer. The quantity of oil is from 6 to 10 pounds per kv-a. rating, or in small sizes 500 pounds per kilowatt loss. There should be from 1.5 to 2.3 square inches of transformer surface (A_t) per watt loss. The oil ducts should be ¼ inch wide and run vertically. If the tank is smooth there should be from 4 to 8 square inches of tank surface (not including top or bottom) for each watt loss. For sizes greater than 25 kilowatts it is

customary to use fluted or corrugated sides to the tank. In this case there should be from 6 to 10 square inches of radiating surface per watt loss because the air does not circulate as rapidly in the grooves as over a smooth surface and consequently radiation is poor.

For a rise of 50° C. of the transformer there is an average rise of 30° of the oil. The maximum rise of the oil is 1.3 to 1.5 times the average.

The rise in temperature of the windings by resistance or of the iron by thermometer is

$$T = \frac{2\,W}{A_t} + \frac{1.4\,tW}{S},$$

where W = total watts lost;

A_t = radiating surface of transformer in square inches;

S = radiating surface of tank in square inches;

t = from 160 to 200 with smooth tanks

= 200 to 270 with corrugated tanks.

Air-blast Transformers. — This type of transformer is usually set over a large air duct in the floor which is supplied by a blower with air at a pressure of from ½ to 1 ounce (¾ to 1½ inch of water). The air enters the transformer at the bottom and is divided into two streams, one passing vertically through the windings and the other transversely through the iron. There is a damper or valve for each stream so that the proper amount of air is provided to each part independently. Ducts ½ inch wide are provided every 3 to 4 inches. For 50° rise the cooling surface of the transformer (A_t) should be from 1.5 to 2.3 square inches per watt loss. A liberal amount of air for 50° C. rise is 150 cubic feet per minute per kilowatt loss. The air is expected to rise from 15° to 20° C. in its passage through the transformer. The theoretical quantity of air in cubic feet per minute is

$$Q = \frac{1.65\,W}{T_a},$$

where T_a is the rise in temperature of the air, which is usually about half as great as the rise of the transformer.

Water-cooled Transformers. — The cooling coils are suspended in the tank in the oil near the top, usually above the transformer, and carry a continually circulating stream of water. It is customary to provide ⅙ gallon of water per minute for each kilowatt of loss and to allow the outgoing water to rise 25° C. above the incoming. Other requirements are from 1 to 1.5 square inches of surface (A_t) per watt loss for 50° C. rise and 1 square inch surface of water coils per watt loss.

TESTING SINGLE-PHASE TRANSFORMERS. — The customary commercial tests on transformers and the best order of making them are: cold resistance, polarity, ratio and checking of taps, impedance, core-loss and exciting current, parallel run, heat run, insulation tests. The efficiency and regulation are calculated from the results of these tests.

Oil-cooled transformers should never be tested or subjected to potential unless they have been filled with oil from which all moisture has been removed.

Examples of test results are given below.

Cold-resistance Measurement. — The cold resistance must be very carefully made as it is used as a basis of calculating the temperature after the heat run. After the transformer has been standing in one place long enough for all of its parts to have reached the same temperature as the surrounding air, a direct current of from 10 to 15 per cent of the rated current of the coils is sent through the windings and the drop measured with a voltmeter. At the same time the temperature of the windings is measured by a thermometer.

Test of Polarity. — This test gives information necessary for connecting several transformers in a bank and have them operate in parallel or on polyphase circuits. Direct current is sent through one winding of a transformer and a d-c. voltmeter connected across the other winding. If the current is stopped, the voltmeter will give a deflection either positive or negative. For similar connection and direction of current on all the transformers of a bank the deflection should be of the same sign. A small current should be used as otherwise the throw of the voltmeter needle may be sufficient to bend it.

Ratio of Turns. — With no load on a transformer the ratio of voltages is the same as the ratio of the turns. Thus, with a known voltage applied to the low-tension winding, the ratio of turns of the two main windings and of the sections between taps can be checked up by connecting across the other terminals another voltmeter of proper range (using a potential transformer if necessary).

Impedance Test. — This test is important in order to calculate the regulation and in order to determine whether transformers will run in parallel with each other. One winding of a transformer is short circuited and a voltmeter, ammeter and wattmeter are connected in the circuit of the other winding. A voltage of from 1 to 8 per cent of the rated voltage of this winding and of the proper frequency is impressed. The voltage is regulated so that readings are taken at values of current from 50 to 125 per cent of the rated current of the winding. The wattmeter reading will be in the neighborhood of 2 per cent of the rating of the transformer. The total impedance of the transformer will be $Z = \frac{E}{I}$. The total effective resistance will be R = Watts/I^2, which will include the effect of eddy currents, and the total reactance will be $X = \sqrt{Z^2 - R^2}$. This reactance cannot be separated into primary and secondary reactance. The results of this test are usually plotted in two curves, one between volts and amperes and the other between volts and watts.

Core-loss and Exciting Current Test. — The alternator supplying the power for this test should give a sinusoidal e.m.f. wave, as any distortion in the shape may cause a variation of from 5 to 10 per cent in the core-loss. A peaked wave gives a lower core-loss than a sine wave. For this test the high-tension winding is left open and rated voltage at the proper frequency is impressed on the low-tension winding. A voltmeter, ammeter and wattmeter are connected in the low-tension circuit, the voltmeter having a range including the rated voltage of the transformer and the ammeter a range of approximately 15 per cent of the rated current of the machine. Readings are taken with a voltage of from 50 per cent to 125 per cent of the rated voltage of the transformer. Both ampere-volt and watt-volt curves are then plotted. If extreme accuracy is desired, the RI^2 loss should be subtracted to give true core-loss.

Separation of Eddy and Hysteresis Losses. — In certain special cases it is desired to investigate the iron of a transformer by separating the hysteresis from the eddy loss. Let

W_1 = the core-loss at normal voltage and frequency.
W_2 = the core-loss at half voltage and half frequency.
W_e = eddy-current loss at normal voltage and frequency.
W_h = hysteresis loss at normal voltage and frequency.

Then

$$W_e = 2\,W_1 - 4\,W_2,$$
$$W_h = 4\,W_2 - W_1.$$

Parallel Run Test. — The tests for polarity and ratio having shown nothing wrong in the transformers, they are connected two at a time, the low-tension windings being connected in parallel to a generator and the high-tension windings in parallel with each other with an ammeter of about 10 per cent the capacity of the transformer connected in one lead between them. The voltage of the alternator is gradually increased from zero and the current in the ammeter noted. This current should not be greater than 5 per cent of the rated current of that winding at rated voltage. If a transformer has double windings in either member the same test should be made on these windings in parallel.

Heat Run. — The heat run is made at the rated load of the transformer and sometimes at an overload of 25 per cent or 50 per cent, depending upon the guarantees. The run may be made by connecting the transformer to a load such as a water rheostat (*q.v.*) but as there are other equally good methods, avoiding the waste of so much energy, this dead load is seldom used. The other methods require two or three transformers to be tested simultaneously.

Two Transformers "Bucking" (Fig. 22). — The low-tension windings of two transformers are connected in multiple to a voltage of rated value and frequency. The high-tension windings are connected up so that their e.m.f.'s oppose or "buck" each other, and are in series with an adjustable source of e.m.f., of rated frequency having a value of from 2 to 5 per cent of the rated voltage of the windings. This "loss-supply" may be either an alternator and transformer, or a potential regulator. The voltage of this source is adjusted so that full-load current circulates in the high-tension windings and thereby induces full-load current in the low-tension windings. It should be realized that although only 2 to 5 per cent of the rated voltage is needed to send the current through the primaries, yet each primary is generating its rated voltage and if there should be a ground anywhere a dangerous potential strain or shock might result.

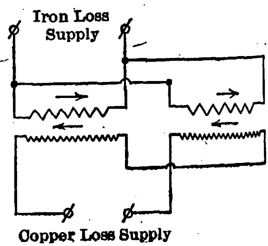

Fig. 22. Connections for Heat Run by Bucking

Three-transformer Arrangement (Fig. 23). — Three single-phase transformers may be connected with their low-tension windings in delta to a three-phase source of supply of proper voltage and with the high-tension windings also connected in delta with one corner open into which the "loss supply" is connected preferably by means of an auxiliary transformer to isolate the dangerous potential of the primaries. The "loss-supply" voltage must be adjusted so that the desired current flows in the primary winding.

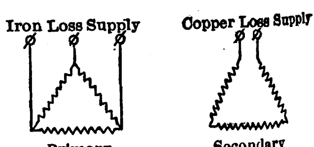

Fig. 23. Heat Run by Open-delta Method

Time for Heat Run. — The time required for a heat run may be considerably shortened by operating at an overload for a short while, or, if the transformer is an air-blast transformer, by operating without the blast until a reasonably high temperature has been attained. Then the proper load is adjusted and the run continued until all temperatures remain practically constant, that is, do not rise more than 1° C. in two hours. The voltage should be cut off once every hour and a resistance measurement quickly made to determine the temperature of the windings.

Temperature Rise by Resistance is calculated from the formula

$$T = (234 + t)\left(\frac{R_h}{R_c} - 1\right),$$

where T = temperature rise in ° C.;
t = temperature in ° C., by thermometer, at which the cold resistance is measured;
R_c = resistance in ohms at temperature t;
R_h = "hot" resistance in ohms at end of heat run.

The number 234 is the reciprocal of the resistivity temperature coefficient (referred to 0° C.), of 100 per cent conductivity copper, i.e., the reciprocal of 0.00427. For any other conductivity, C per cent say, divide 234 by $C/100$. *(See article on Resistance and Conductance.)*

Temperature Rise by Thermometer. — In an air-blast transformer it is desirable to measure by thermometer the temperature of the incoming air, of the outgoing air (from iron and coils), of the primary windings, and of the secondary windings. Spirit thermometers and not mercury thermometers should always be used for measuring the temperature of transformer windings. In an oil-cooled transformer the temperature, by the thermometer, of the tank at top and bottom and of the oil in two or three places near the top should be taken.

Insulation Tests. — To test the insulation between turns and sections of coils double the rated voltage per section is impressed on each section for one minute. This test should be made at a high frequency, preferably at double the rated frequency. After this one and a half times normal voltage at rated frequency is applied for five minutes, to discover the effects of the double voltage test. These voltages should be applied and removed gradually.

High-potential Test on Complete Transformer. — To test the dielectric strength of the insulation as a whole the following high-potential test is made. Connect both terminals of the high-tension winding to one terminal of the high-potential transformer. Ground both ends of the secondary winding to the core and frame and connect to the other terminal of the high-potential transformer. Adjust a needle gap to arc at the desired test voltage and increase the voltage gradually until the gap arcs over. Decrease the voltage till the arcing ceases and hold the voltage as near as possible to the arcing point for one minute. The voltage should then be decreased gradually. The proper testing voltages and spark-gap adjustments are given in the Standardization Rules of the A.I.E.E. (q.v.).

Calculation of Efficiency and Regulation from Test. — From the results of the preceding tests the efficiency and regulation of the transformer at various loads may be calculated by the methods given above, p. 1625 in the paragraph on *Efficiency and Regulation,* using the test data instead of the calculated quantities.

TESTING OF THREE-PHASE TRANSFORMERS. — In testing three-phase transformers the same methods are followed as with single-phase units. The only difference is in testing for polarity; owing to the mixing of the magnetic circuits special care must be exercised. The direct current must be sent in one direction through one primary phase and in the opposite direction through the other two, so that they will not neutralize one another. With a voltmeter similarly connected on the primary and secondary of each phase in turn, break the direct current; if the connections are right the voltmeter on the secondary will deflect in the same direction as the steady deflection on the primary.

Parallel Run. — For the parallel run of two three-phase transformers, connect their low-potential sides in multiple to a source of three-phase potential. Connect together the primary terminals No. 1 of both transformers and bring the pairs of terminals No. 2 close together so they may be connected by a small fuse wire. If no spark is noticeable when the fuse wire spans the connection, then the No. 2 terminals may be permanently connected. The same procedure is followed with the No. 3 terminals.

EXAMPLES OF PERFORMANCE. — Usual values of the performance characteristics of transformers are given below.

Exciting Current ranges from 2 to 6 per cent of full-load current in lighting transformers of the core type and from 5 to 10 per cent in power transformers.

Core-loss ranges from 0.5 per cent to 1.25 per cent of the rated output.

Total I^2R ranges from 0.75 per cent in large sizes to 2 per cent in small sizes of the rated output.

Total Reactance drop ranges from 1.25 to 5 per cent of the voltage, being less for the shell type than for the core type. The value depends largely on the purpose of the transformer, methods of construction and opinion of the designer.

Efficiency and Regulation. — The variation of the efficiency with the load of two small 60-cycle transformers for lighting purposes is shown in Fig. 24. The

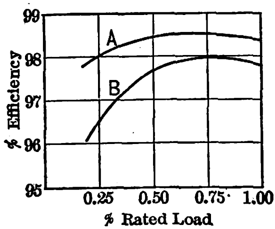

Fig. 24. Efficiency of 60-Cycle Transformers. A = 50 Kv-a.; B = 10 Kv-a.

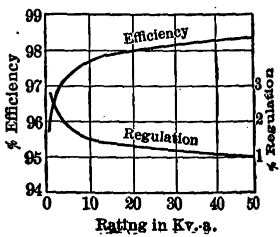

Fig. 25. Efficiency of a Line of 60-Cycle Transformers

efficiency and regulation at full load of a line of these transformers is shown in Fig. 25. These transformers are small and of the core type. Larger transformers would have even better characteristics.

See also above under *Examples of Design*.

SPECIFICATION FOR TRANSFORMERS.* — The following memoranda are intended to assist in writing specifications. See also article on *Specifications*.

Principal Characteristics and Conditions of Service. — Service for which transformer is to be used, e. g., operating synchronous converters, induction motors, lights, etc. High- and low-tension voltages at normal load. Taps for obtaining different voltages. Rating in kilovolt-amperes and in kilowatts at stated power factor. Frequency.

Style and Description: Details of Construction. — Whether oil-, air- or water-cooled. Style and location of terminals. Where line surges are likely to occur, it is usual to specify, for large transformers, that the end turns, say 10 per cent of the total turns at each end, shall have extra heavy insulation.

Work to be Done by Other Contractors. — Who is to supply and install floor framing and supports; high- and low-tension wiring, wiring and supports for delta- or star-connections, if to be used three-phase.

* By W. A. Del Mar.

Performance and Tests. — (*See Standardization Rules of the A.I.E.E.*) Temperature rises upon which ratings are to be based. Details of overload capacity. Efficiency at 25, 50, 75, 100, and 125 per cent load with stated transformation ratio. High-potential tests of insulation. Requirements regarding effect of moisture and heat on insulation, such as the following: The transformers shall contain no material which will be permanently injured by moisture or by an occasional temperature of 95° C., provided that this temperature is not maintained at any one time for a period greater than 3 hours. The transformers shall be capable of operating continuously at 80° C., without the insulation being damaged thereby. Regulation with rated non-inductive load. Regulation with load of rated kilovolt-amperes at stated power factors, say 100 per cent and 90 per cent. State formula by which regulation is to be calculated. Reactance between primary bus and secondary terminals when transformers are to operate compound-wound synchronous converters. (The required reactance is usually specified by the manufacturers of the synchronous converter.) Amount of air or water for cooling, in cubic feet per minute at stated pressure. After the transformer has been in service for one year, its efficiency at full load shall be not lower than the above guaranteed amount by more than a stated percentage and after two years its efficiency shall be not lower than the guaranteed amount by not more than a stated percentage.

INSTALLATION OF TRANSFORMERS. — Transformers require no special foundations but merely a level floor of sufficient strength to carry the weight. Provision should be made for an electrical connection from the tank of the transformer to the ground.

Oil- and Water-cooled Transformers. — The greatest enemy to successful operation of transformers in general, and high-voltage transformers in particular, is moisture, in that 0.1 per cent of moisture in oil renders it unfit for use. This may result either from rain or dripping water falling into the transformer or onto some of the parts, or from the condensation of the moisture in the atmosphere on the various parts. For this reason all parts of a transformer must be very carefully inspected, cleaned and dried before the transformer is put into service. If the operating potential is 15,000 volts or less an inspection will tell whether the transformer should be dried, but for voltages greater than 15,000 the drying operation should be carried out in every case.

Methods of Drying. — The best method of drying is to send a current of dry air at 90° C. through and around the transformer. This should continue for 24 hours in all transformers, for 72 hours in high-voltage transformers of reasonable capacity and longer in special cases. Another method of drying is to short-circuit one winding of the transformer and to apply to the other member a voltage of from 1 to 2 per cent of the rated voltage of that winding so that a current of from ⅙ to ⅛ of the rated value flows through the winding. This current should be adjusted so that a spirit thermometer placed on the low-tension coils shows a temperature of 80° C. and not greater.

Preparation of Oil. — No potential should be applied to any oil-cooled transformer unless it is supplied with a proper amount of oil as the oil forms the essential insulating medium as well as cooling medium. The oil should be tested before using. Oil is considered in good condition when it will withstand 40,000 volts between disks ½ inch in diameter and $\frac{2}{10}$ inch apart. Transformers for 40,000 volts or less will operate satisfactorily when this dielectric strength has dropped to 25,000 volts, but when this condition has been reached the oil should be dried, purified and strained. Transformers for a voltage greater than 40,000 should not be used with oil which breaks down under 35,000 volts in the above described test apparatus. A special apparatus for

drying and purifying the oil is on the market (*see G. E. Bulletin No. 4134*). See also article on *Oil, Transformer*.

The transformer tanks should be filled by pouring the oil through a fine-cloth strainer and allowing the oil to settle 12 hours before using. Rubber tubing should not be used for carrying the oil as the sulphur in the rubber will eventually cause trouble. The cover of the transformer should prevent any water dripping into the transformer but there should be a free exit allowed for gases which may gather. If the transformer stands in a moist atmosphere a special "breather" containing calcium chloride should be employed. In all transformers the level of the oil should be well above the top of the transformer proper and this should be noted 2 or 3 days after the original filling to see whether the transformer windings have absorbed sufficient of the oil to lower the level a dangerous amount.

Certain small sizes of oil-cooled transformers are designed to be suspended from cross arms on poles or the sides of buildings or to be installed in manholes in a subway. These transformers are especially protected against the weather.

Precaution Against Overheating.—It is most important to be assured of the proper circulation of the cooling medium as the temperature of the transformer will rise quickly to an excessive value in case of a failure of the cooling medium. In this case the load must be reduced and kept at such a value that the temperature of the oil at the top does not exceed 80° C. If at any time the oil reaches an excessive temperature there will be a tendency for a deposit to form on the transformer and coils, which will interfere with the proper cooling. An inspection should be made occasionally for this purpose and the deposit removed. The oil should be sampled and tested each week for the first month and every six months thereafter. In taking samples of the oil great care should be exercised that the vessel in which the sample is contained is perfectly dried. The temperature of the oil in a self-cooled transformer should never exceed 80° C. and in a water-cooled transformer 65° C. Oil-cooled transformers must be in a well-ventilated compartment in which the air should not be more than 5° above the outside atmosphere. An inspection should be made from time to time to see that there is no condensation on the inside walls of the tank.

Precaution for Multiple Operation.—Transformers should never be connected in multiple on the secondary side without proper precautions having been taken to determine not only that the polarity is correct but that the regulation of the two transformers is the same.

Air-blast Transformers; Ducts and Blower Set.—Air-blast transformers should be placed over an air duct of sufficient size to permit the required current of air to flow at a velocity of less than 500 feet per minute. The duct should be of non-combustible material and should have smooth sides in order to offer very little resistance to the current of air. Air is supplied to this duct by means of motor-driven blowers of capacity to supply the proper quantity of air for a group of transformers at pressures from ½ to 1½ ounces (*see Blowers and Compressors; Fans*). Roughly the rating of the blower motor in horse-power is equal to

$$\frac{(\text{Cubic feet of air per minute}) \times (\text{pressure in ounces})}{1200}.$$

The air enters the transformer at the bottom, flows vertically through the coils and passes out at the top, and also flows transversely through the iron, passing out at the side. Separate dampers at each outlet are provided in order to regulate the two currents independently. The dampers are regulated so that the outgoing air has a temperature 20° above the incoming air.

Since the transformers are so dependent on the air blast for their operation and safety, it is customary to provide a reserve blower set.

Location. — Care must be exercised to protect the transformers from moisture and dirt and particularly, since they are open at the top, to place them where water and dirt cannot drop in the open top. All terminals of the air-blast type of transformer are usually brought out below so that the primary and secondary cables may be laid in the air duct and all connections and inspection may be made from below. It is therefore desirable that the air duct be sufficiently large to enable a man to move about therein.

Drying and Cleaning. — In putting the transformer in operation all moisture must be removed before applying potential. This may be accomplished by running the blower set and forcing air through the transformers, which will be sufficient if the air is dry. Another method is to short-circuit one winding of the transformer and apply a low voltage of from 1 to 2 per cent of the rated voltage to the other winding, so that 75 per cent of full-load current flows through the windings. This is maintained for from 24 to 36 hours. All transformers of this type should be cleaned once a month by means of compressed air at 20 pounds pressure.

Measurement of Temperature. — In determining the temperature of the windings only that calculated from a resistance measurement is dependable, as the coils are so thickly wrapped in insulation that a thermometer will not show the true temperature.

OPERATION OF TRANSFORMERS. — Single-phase transformers may be used singly or in parallel on single-phase circuits, and in various combinations on polyphase circuits as described above. The polarity should be determined before making the connections.

Parallel Operation on Single-phase Circuits. — Single-phase transformers are very generally operated with the primaries in parallel on the supply circuit and their secondaries in parallel on the load circuit. In order to successfully operate in this manner two or more transformers, the transformers must have: (1) the same ratio of transformation; (2) the same regulation; and (3) the same value of X/R, where R and X are the total resistance and reactance respectively of any one of the transformers. Transformers divide the load inversely proportional to their reactances, provided the ratio of reactance to resistance is the same in both cases. If transformers are purchased to operate in parallel with others, proper provision must be made in the design of the transformers, and this fact should be stated in the specifications.

In general, a 50-kilowatt transformer will have about twice the resistance and twice the reactance of a 100-kilowatt transformer of the same commercial line, and therefore these transformers will divide the load in proportion to their capacity. But this is not likely to be true of transformers of different lines or made at widely different times.

If transformers not satisfying the above conditions are to be run in parallel, an impedance coil having a proper resistance and reactance may be connected in the circuit of one of them, thus establishing the necessary conditions for the proper distribution of load, provided the ratios of transformation are the same.

Transformers on Polyphase Circuits. — See section above on *Transformer Connections*.

WEIGHTS AND COSTS. — The curves of Figs. 26 to 29 inclusive give approximate values of the weights and costs of several representative lines of single-phase transformers of the most usual common capacities, voltages and frequencies. These values are sufficiently accurate to be used in preliminary

estimates, plans, theses, etc. The actual prices, however, vary with the price of copper, commercial conditions and special guarantees.

The weight given is that of the transformer complete including case and oil, if any, but does not include the boxing for shipping.

The cost is given in the form of dollars per kv-a. rating and with the exception of the lighting transformers of Fig. 26 this kv-a. means the output which could be obtained in continuous operation with the maximum rise in temperature of 40° C. The transformers of Fig. 26 are of the lighting type and their rating is based on the characteristics of a lighting load, which is roughly a guarantee of a maximum rise in temperature of 50° with a load of this character. The prices include the cost of the oil.

The cost per kv-a. and weight per kv-a. of three-phase transformers are roughly 90 per cent of the cost and weight per kv-a. of 3 single-phase transformers having a combined capacity equal to that of the three-phase transformer.

The voltage of the secondary may vary in all cases from 110 to 440 without appreciably affecting the cost or weight given.

TRANSFORMERS, INSTRUMENT. — (*See also Transformers.*) Instrument transformers are either potential transformers or current transformers. Potential transformers are transformers of comparatively small output arranged for shunt connection to the primary lines, designed to produce a secondary voltage which accurately represents the primary voltage for application to instruments. Current transformers are transformers of comparatively small output arranged for series connection in the primary lines, designed to produce a secondary current which accurately represents the primary current for application to instruments. The insulation of both current and potential transformers is designed with reference to the voltage of the circuit on which the transformer is to be used. The most common voltage for the secondary of the potential transformer is 110 volts. The most common current for secondary full load on the current transformer is 5 amperes. The secondary voltage of the current transformer is usually very low under operating conditions, being only sufficient to force the secondary current through a few instruments of low impedance.

APPLICATIONS. — Instrument transformers are used for three principal purposes: (1) to supply current and voltage to measuring apparatus; (2) to operate regulating devices; (3) to operate circuit protective devices. In each case there are two principal advantages to be attained by the use of transformers: (1) to protect the devices in the secondary circuit against the inconvenience or danger of a direct application of the primary voltage or current; (2) to enable the use of measuring, regulating and protective devices designed for one standard current and voltage for the entire range of currents and voltages used under various operating conditions, thus simplifying design and manufacture, increasing reliability and accuracy and lowering cost.

Accuracy and Reliability Required. — Of the three applications given above that involving measuring instruments requires the highest accuracy in the transformer; in the operation of regulating devices the certainty of continuous operation is more important; in the operation of circuit protective devices, a very moderate degree of accuracy is satisfactory, but certainty of operation is of the highest importance. It is, therefore, frequently desirable to use different transformers for the several purposes, even where convenience and cheapness would suggest the use of a single transformer.

THEORY OF CURRENT TRANSFORMER. — The current transformer consists of a primary winding in which the line current flows, a core, and a secondary winding for connection to a load of instruments and other devices connected in series. The current flowing in the primary is usually unaffected by the characteristics of the transformer or by the amount of secondary load. With the secondary winding short-circuited, the secondary ampere-turns are nearly equal to the primary ampere-turns, the slight difference being due to the relatively small exciting current (*see Electricity and Magnetism, Principles of*). This exciting current is always of low power factor, while the power factor of the secondary current depends on the resistance and inductance of the secondary circuit. While the reversed secondary ampere-turns always equal the primary ampere-turns less the exciting ampere-turns, the subtraction of the exciting ampere-turns is not usually arithmetical but vectorial, and the resulting secondary ampere-turns are less than and not in exact phase opposition to the primary ampere-turns. This is expressed by stating that the transformer current ratio varies from the ratio of turns, and that there is a phase angle between the primary and reversed secondary currents. Since these errors depend on the relative amount of the exciting current and its phase position with respect to the secondary current, they will vary with the imped-

ance of the secondary load and the current flowing through it. When the impedance becomes so great that the transformer core approaches saturation, the exciting current becomes so large that the secondary current is no longer proportional to the primary current and also differs from it appreciably both in wave form and phase position.

Ratio and Phase Angle. — For accurate current measurements through the intermediary of a current transformer the exact ratio of the primary to the secondary current must be accurately known. For power measurements the phase angle between the two currents must also be accurately known.

Let

u = ratio of the number of secondary to the number of primary turns,

I_p = primary current,

I_s = secondary current,

k = ratio of exciting current to the secondary current,

α = phase angle between the exciting current and primary induced e.m.f.,

θ = phase angle between the secondary current and secondary induced e.m.f. (positive for lagging current),

β = the "phase angle" of the transformer, i.e., the angle between the primary current and the secondary current reversed. If the power factor of the secondary impedance load is higher than that of the exciting current, the secondary current (reversed) leads the primary current and β is positive; if the power factor of the secondary impedance load is lower than that of the exciting current, the secondary current (reversed) lags behind the primary current and β is negative.

Then the ratio of transformation is

$$\frac{I_p}{I_s} = u\sqrt{(\cos\theta + k\cos\alpha)^2 + (\sin\theta + k\sin\alpha)^2}$$

and the phase angle is

$$\beta = \tan^{-1}\frac{k\sin(\alpha - \theta)}{1 + k\cos(\alpha - \theta)}.$$

The value of the ratio k for a given primary current depends upon the impedance of the load connected to the secondary; the higher this impedance the greater the value of k and therefore increasing the impedance of the secondary connected load tends to increase the difference between the ratio of turns and the true ratio of the primary and secondary currents; increasing the impedance of the secondary also tends to increase the phase angle β of the transformer. The true ratio $\frac{I_p}{I_s}$ and the phase angle β also depend upon the power factor of the load. For the actual variation of these quantities see Figs. 1 to 4, below.

THEORY OF POTENTIAL TRANSFORMER. — The potential transformer consists of a primary winding, a core and a secondary winding. The primary winding is placed across the line, and the secondary winding is connected to instruments or other devices connected in multiple. The voltage across the primary is usually unaffected by the characteristics of the transformer or of the secondary load. With the secondary open the secondary terminal voltage is approximately equal to the primary impressed voltage divided by the ratio of the number of turns in the primary to the number of turns in the secondary, the difference being due to the impedance drop produced in the primary by the exciting current. The impedance drop in the primary due to exciting current is usually not in phase with the primary voltage; hence its subtraction in a vector relation from the primary voltage results both in a variation of the voltage ratio from the ratio of turns and in a difference of phase

between the primary and reversed secondary voltages. This no-load ratio and phase angle are modified under load conditions by the additional impedance drop in the primary and secondary windings due to the load current. The less the impedance of the load the greater will be the current through the two windings of the transformer, and therefore the greater the impedance drops in these windings; hence the greater will be the discrepancy between the actual ratio of the terminal voltages and the ratio of turns. As the impedance drop due to the load current may be in almost any phase, whereas the drop due to exciting current bears a constant relation to the induced voltage, the phase angle with loads of various power factors may be either less than or greater than that at no load.

Ratio and Phase Angle.—For accurate voltage measurements through the intermediary of a potential transformer the exact ratio of the primary to the secondary terminal voltages must be accurately known. For power measurements the phase angle between the two voltages must also be accurately known. The expressions for these two quantities in terms of the constants of the transformer and the impedance and power factor of the total instrument load connected to the secondary of the transformer are quite complicated. The relations involved in the expression for the true ratio may be expressed as follows:

Let u = ratio of number of turns in primary to number in secondary winding,
E_p = primary impressed voltage,
E_s = secondary terminal voltage,
E = secondary induced e.m.f.,
I_p = primary current,
I_s = secondary current,
Z_p = primary impedance,
Z_s = secondary impedance.

Then

$$\frac{E_p}{E_s} = \frac{uE + Z_pI_p}{E - Z_sI_s},$$

where the numerator and denominator of this fraction are a *vector sum* and *vector difference* respectively, and E, I_p and I_s depend upon the voltage, impedance and power factor of the load, and the value of the exciting current. (*See article on Transformers.*) For actual variations in the true ratio $\frac{E_p}{E_s}$ with the power factor, voltage and volt-amperes of the load on the secondary see Figs. 5 and 7.

The phase angle γ of a potential transformer, i.e., the angle between the primary terminal voltage and the secondary terminal voltage reversed, may range from a positive angle (secondary voltage lagging behind primary voltage) to a considerable negative angle (secondary voltage leading primary voltage), depending on the relations of the impedance and power factor of the secondary connected load, the secondary winding, and the primary winding and on the exciting current. Under the no-load condition this angle is nearly always negative, and at high core densities where the exciting current is large and of very low power factor, it may be very large. The general tendency of non-inductive secondary loads is to cause γ to vary in the positive direction (secondary voltage to lag) and of inductive (lagging current) loads to cause it to vary in the negative direction (secondary voltage to lead). It is frequently possible to bring γ practically to zero for a single voltage and load by adding a non-inductive load in suitable amounts. See Figs. 6 and 8 for actual variations in the phase angle γ with the voltage, power factor and volt-amperes of the load on the secondary.

DESIGN. — The general principles of design of instrument transformers are the same as for power transformers. The special uses of the instrument transformers, however, change the details of design to a considerable degree.

Design of Current Transformers. — A very important purpose of current transformers is the operation of protective devices. For this reason the failure of the current transformer may cause destruction of expensive apparatus, and they are therefore designed to stand a higher insulation test than other types of transformers. Again, the exciting current of the current transformer has direct relation to the phase angle and errors of ratio. The flux density in the core is therefore kept very low for the ordinary metering conditions, in order to keep errors within satisfactory limits. The resistance and leakage reactance of the primary winding do not affect the ratio of the transformer nor the phase angle between primary and secondary currents; their only effect is on the total impedance in the primary line. Resistance and leakage reactance in the secondary constitute definite additions to the secondary load, and affect the phase angle and ratio of the transformer. As the current rating of a current transformer is always greater than the maximum continuous current to be carried by the lines of which it is a part, no considerable overload capacity is required.

A suitable design for current transformers, therefore, should include:

- High factor of safety in insulation,
- Low density of flux under the conditions of metering service (this is best secured by a moderate cross-section of core with a relatively large number of turns),
- Low resistance and leakage reactance in the secondary winding,
- Resistance and reactance of the primary winding low enough so that the impedance will not cause an objectionable drop in voltage in the primary lines, when the transformer is to be used in low voltage circuits.

Special Designs of Current Transformers. — For certain special purposes special designs are useful. In stations where very large power is on the bus-bars while small power circuits, such as station auxiliaries, are drawn from the same bus-bars, current transformers must be used which are adapted to operate on small current, while under enormous extremes of current the transformers must at least remain in service long enough to operate the protective devices. Where the currents are not too low, transformers with a single copper bar as primary may be used. These resist mechanical injury from short-circuit, but the number of ampere-turns under the ordinary load conditions is limited to the number of amperes flowing in the primary line. Hence these transformers have an accuracy suitable for metering purposes only where the rated current of the line is comparatively large. When the normal currents are too low for satisfactory operation with a single primary turn, special transformers of large size, great primary current capacity and reduced accuracy are sometimes used.

A somewhat similar case arises where the cost of current transformers for use in high-tension circuits is prohibitive. A transformer is then placed on the bushing of an oil switch, the lead inside the bushing being the primary, and a secondary being wound on a core which encircles the bushing. As the primary current is usually small, while the length of the magnetic circuit is comparatively large, the accuracy of these transformers is low, and their use is ordinarily confined to tripping devices or specially calibrated ammeters.

Design of Potential Transformers. — The design of a potential transformer is very similar to that of a small power transformer. To obtain accuracy of ratio and small phase angle between primary and secondary voltages, the flux density in the core should be kept comparatively low. The resistance and leakage reactance of the primary and secondary should be kept small. As these trans-

formers are ordinarily connected to the line through fuses, their insulation is sufficient if it equals that of good power transformers for the same voltage. The exciting current is usually a larger fraction of the full-load current than in power transformers, because efficiency is a matter of no moment, and good regulation is necessary. The no-load phase angle, however, is roughly dependent on the product of the exciting current by the primary resistance; hence too large an exciting current or too large a resistance is undesirable.

RATING AND PRECISION. — The watt or volt-ampere rating of instrument transformers as given by many manufacturers is purely formal, and has only the most distant relation to the characteristics of the transformer. There is no general correspondence between accuracies of transformers produced by various manufacturers for the same load. Where transformers are designed with oil immersion for high-voltage circuits, their quality is less likely to be poor than in the small types without oil, because the proportionate difference in cost of manufacture between good and poor transformers is then comparatively small.

Precision of Current Transformer. — The variation of ratio and phase angle with the load on the secondary of two typical 2300-volt, 20 : 1 ratio, cur-

rent transformers is shown in Figs. 1 to 4. Figs. 1 and 2 show curves of ratio and phase angle obtained from tests on a current transformer (No. 1) of low flux density, high ampere turns, and comparatively low secondary resistance and leakage reactance. Figs. 3 and 4 show the results of similar tests on a current transformer (No. 2) where these values are not so strictly limited. It should be noted that the scales of $\frac{\text{true ratio}}{\text{marked ratio}}$ and of phase angle in Figs. 3 and 4 are four times those used in Figs. 1 and 2.

Each pair of curves was made with a different load on the secondary, loads consisting of a series of combinations of instruments, watt-hour meters, and switchboard devices representing conditions in ordinary practice. Table I gives the volt-amperes and power factor of the loads, designated by the letters

A to *D*, at 60 cycles and 5 amperes and also the corresponding inductance and equivalent resistance components.

TABLE I

LOADS REFERRED TO IN FIGS. 1 TO 4

Load	Volt-amperes, load at 60 cycles and 5 amperes	Power factor at 60 cycles and 5 amperes, per cent	Equivalent resistance, ohms	Inductance, milli-henries

tial transformers is shown in Figs. 5 to 8. Figs. 5 and 6 show the curves of ratio and phase angle obtained in test on a potential transformer (No. 1) in which the flux density is low, and the resistances and leakage reactances of the wind-

ings are within moderate limits. Figs. 7 and 8 show the results of similar tests on a transformer (No. 2) of the same rating in which these quantities reach larger limits, resulting in inferior regulation and larger phase angle.

GENERAL TESTS DURING MANUFACTURE. — As the last step in manufacture the insulation of every current or potential transformer should be tested at a voltage greater than that at which it is to operate, the actual voltage selected being determined by the A.I.E.E. Standardization Rules. Some manufacturers find it desirable to apply considerably higher test voltages than these to insure additional safety. A sufficient number of each type should be given heating tests to assure safety of operation for the entire group. A check on accuracy should be made on all transformers to protect against errors in counting turns, short-circuits, etc.

TESTING OF CURRENT TRANSFORMERS FOR RATIO AND PHASE ANGLE. — Where large numbers of current transformers are to be tested to a high degree of accuracy for ratio and phase angle, those methods which use primary and secondary shunts, balancing the voltage drop through a zero reading instrument, are most rapid and satisfactory. The care and expense of such an outfit is justified only where a large number of transformers must be carefully tested. The phase angle may also be determined by the use of two wattmeters or electrodynamometers. Where transformers are in use and require an occasional check to determine that they have not changed in characteristics, a simple method which covers most cases is to compare the ratio with that of a standardized portable transformer. These methods are described below.

The uniformity among transformers of a certain type, make and size is usually very good; in the case of a large lot of transformers detailed tests need be made only on a few representative ones.

Demagnetization of Core Before Testing. — The cores of current transformers should be demagnetized before the test for ratio or phase angle is made. With small low-voltage current transformers demagnetization may be carried out by putting at least one-half-load primary current through the transformer with 10 ohms or more connected to the secondary in series with the instruments to be used. With large high-voltage current transformers having massive cores the resistance should be several times greater to assure perfect demagnetization. This resistance should then be gradually reduced to zero by steps of one ohm or less.

When however current transformers are subjected to test in order to use the results for the correction of observations already taken, the tests should be made in such a way as to avoid changing the magnetic condition of the core before the test results are secured. The secondary should have no greater load than that used in the working condition, and especial care should be taken that current is not allowed to flow in the primary or the secondary while the other winding is open circuited. The current should be brought up to the lowest current point first, and raised to the higher points only after the lower readings have been made.

Frequency of Test Current. — In all current-transformer work where results of test are to be used for correction, the frequency used in test should be the same as that of the circuit in which the transformer is to be employed. When the intention is only to check the condition of the transformer, any commercial frequency may be used.

Shunt Methods of Testing Current Transformers. — The following is a description of the details of one of these methods which has been found satisfactory in use.

Apparatus. — Referring to Fig. 9 a three-phase supply is used to excite a phase-shifting transformer with a single-phase secondary. The supply of current to the transformer under test is obtained from one phase of the same source through a control resistance R_1 and a step-up current transformer. For small ratios the step-up transformer is omitted. Its input side is wound to use up to the voltage of the supply (125 volts). The high-current winding consists of heavy loose cable, of which one or more turns may be wound through the large core opening. By suitably selecting the number of turns, currents from 10 to 4000 amperes are obtained. The primary shunt has a resistance such that full rated current gives a drop of 0.5 volt. It is arranged to carry 50 per cent overload current for a short time for testing purposes. The secondary shunt is adjustable, and is marked in percentage of a normal resistance. By the use of several interchangeable scales the normal resistance corresponding to 100 per cent may be made 0.06, 0.075, 0.08, 0.1, 0.12, or 0.125 ohms. These allow the use of a primary 100-ampere shunt of 0.005 ohms resistance for transformers of 12 : 1, 15 : 1, 16 : 1, 20 : 1, 24 : 1 and 25 : 1 rated ratios, while still obtaining a direct reading on the secondary scale of the $\frac{\text{true ratio}}{\text{marked ratio}}$ of the transformer. A set of primary shunts rated 5, 10, 20, 50, 100, 200, 500, 1000, 2000 and 5000 amperes will thus cover all probable ratios from 1 : 1 to 1250 : 1. M is an adjustable calibrated mutual inductance whose current coil is in series with the secondary of the transformer under test, and whose potential coil is in series with the potential element of the sensitive electrodynamometer D, whose current element in turn is supplied from the secondary of the phase-shifting transformer mentioned above. Z is a double-throw single-pole switch. L is a series of secondary loads suitable to represent the instrument combinations usually found in practice.

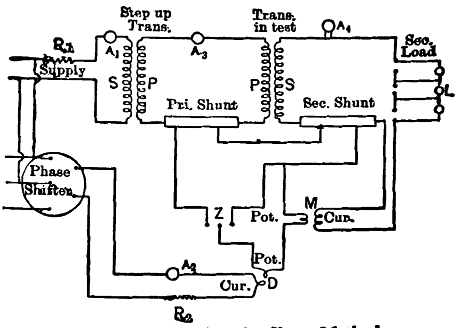

Fig. 9. Connections for Shunt Method

Procedure. — In making the test the procedure is as follows: The proper load is connected to the secondary of the transformer, and the primary current is adjusted to the proper point by means of the resistance R_1. This current may be read by an ammeter and separate current transformer at A_3, or by an ammeter at A_4 which is short-circuited after reading. The switch Z is closed to the right. The mutual inductance then acts as an air-core transformer, supplying to the dynamometer potential element a voltage in quadrature with the secondary current of the transformer under test. The phase of the field current of the dynamometer is then adjusted to the point where the dynamometer reads zero for all positions of the mutual inductance. This is the position of maximum sensibility to changes in the resistance of the secondary shunt. The switch Z is then thrown to the left, and the resistance drop of the secondary shunt is adjusted by moving the drop contact until the dynamometer reads zero. The phase of the dynamometer field current is then shifted through 90 electrical degrees by moving the handle of the phase-shifting transformer a

definite distance. This is the position of maximum sensibility to phase-angle variation. The mutual inductance is then adjusted until the dynamometer reads zero. The phase of the field current is then shifted back to the previous position, and a slight readjustment of the secondary shunt resistance made if necessary.

Calculations. — From the reading of the mutual inductance the phase angle is determined by the formula

$$\beta = \tan^{-1} \frac{2 \pi f M}{R_s},$$

where f is the frequency of the circuit in cycles per second, M is the mutual inductance in henries, and R_s the resistance of the secondary shunt in ohms. Then the true ratio is expressed by the formula

$$\text{Ratio} = \frac{R_s}{R_p} \times \frac{1}{\cos \beta},$$

where R_p is the resistance of the primary shunt.

The correction factor $\frac{1}{\cos \beta}$ for $\beta = 1^0$ is 1.00015, and for $\beta = 2^0$ it is 1.0006. At these values it is negligible in comparison with ordinary errors arising in measurement work involving transformers and instruments. If the phase angle is so great that this correction becomes important, the transformer is so inferior that it should not be used for any purpose involving accurate measurement.

Speed of Operation. — By this means a single operator can take about 30 points of ratio and the same number of phase angle per hour. With a helper to perform necessary calculations and a suitable means of rapidly replacing transformers in the circuit, it is quite practicable to make from 15 to 30 tests of transformers including from 6 to 12 points each of ratio and the same number of determinations of phase angle in an eight-hour day. Checks of single points can be made practically as fast as the transformers can be connected and the current and secondary load adjusted.

Standardized Transformer Method for Determining Ratio of Current Transformer. — A portable transformer with four primary coils arranged for series-multiple connection, giving ratios of 5 : 1, 10 : 1, and 20 : 1 will cover practically everything up to 100 amperes. A second portable transformer without primary, so arranged that one turn through the core gives a rated ratio of 200: 1, and more turns a correspondingly lower ratio, will cover from 100 to 1000 amperes. In testing, the primary windings of the transformer under test and the standardized portable transformer are connected in series. Either ammeters or wattmeters may be used as indicating instruments, the latter being susceptible of giving the higher precision.

Use of Ammeters with Standardized Transformer. — The secondary of the standardized transformer is connected to a standardized 5-ampere ammeter, and that of the transformer under test to a similar ammeter and a suitable secondary load. With a sufficient current flowing to give satisfactory readings on the ammeters, readings are made; the ammeters are interchanged, and readings are repeated, to eliminate difference between the instruments. From the mean of the results and the ratio of the standardized transformer, the ratio of the transformer under test is obtained.

Use of Wattmeters with Standardized Transformer. — The two transformer secondaries are connected to the current coils of the wattmeters and the potential elements are placed in multiple and supplied with a definite

voltage from a phase-shifting transformer. The phase shifter is adjusted at each point to cause the wattmeter connected to the standardized transformer to read a maximum. The instruments then are read as ammeters, using a calibration made with the same voltage applied to the potential element. By this means a larger deflection is obtained for low-current values, and consequently greater accuracy. If only transformers of moderate-current rating are tested, so that the current may be kept nearly in phase with the supply voltage by the use of series resistance, the phase-shifting transformer may be omitted and the wattmeter potential circuits excited from the supply voltage.

This method requires little apparatus or care beyond that necessary for keeping instruments and transformers in good condition. It does not test phase angle, but gives a check on ratio, whose error may readily be kept within 0.3 per cent. This includes the error of comparison, using ordinary care, and the error of the standard transformer. It is reasonably convenient and rapid, and is well adapted for use in the laboratories maintained by most companies supplying light and power.

Two-dynamometer Method of Determining Phase Angle of Current Transformers. — Phase angle may be determined (where primary currents are not too great) by the use of similar types of dynamometer wattmeters whose current elements are connected in the primary and secondary circuits, and whose potential elements are supplied in multiple by a phase-shifting transformer. The phase of the voltage is shifted until the primary wattmeter indicates zero, showing a quadrature relation of its current and voltage. If W is the watt reading of the secondary wattmeter, E the voltage applied to its potential element, and I the current in its current coil

$$\beta = \sin^{-1} \frac{W}{EI}.$$

The sensibility of this method is very low with ordinary portable wattmeters, but quite satisfactory with sensitive reflecting dynamometers. It is the best method in use for the accurate determination of phase angle.

Other Methods of Testing Current Transformers. — Many modifications of the above methods and other entirely different methods are in more or less satisfactory use in various laboratories.

TESTING POTENTIAL TRANSFORMERS FOR RATIO AND PHASE ANGLE. — Where a large number of potential transformers are to be tested, the potentiometer method of testing ratio is very satisfactory. In this method the low-tension voltage is balanced against a part of the drop through a large resistance in which current is maintained by the high-tension voltage. This may be combined with the two-dynamometer method of testing phase angle between primary and secondary voltages. Where the number of transformers to be tested is not large, and where only a few ratios are to be tested, they may be compared with standardized transformers, and the phase angle determined by the use of the two-dynamometer method. The ratio may also be determined by the use of a voltmeter and high-resistance multiplier. These methods are described below.

Potentiometer Method of Testing Potential Transformers. — The following is a description of the apparatus and method of procedure which has given satisfactory results.

Apparatus. — The general connections of such an outfit are shown in Fig. 10. The supply is 3-phase for the excitation of the phase-shifting transformer P. One phase is connected through a voltage regulator Q to the low-tension side of the step-up transformer T_1, which has a sufficient number of

connections to provide the range of voltages required for testing. This supply excites the high-tension side of the transformer T_2 which is under test. r_2 and r_1 are placed across the high-tension circuit in multiple with the high-ten-

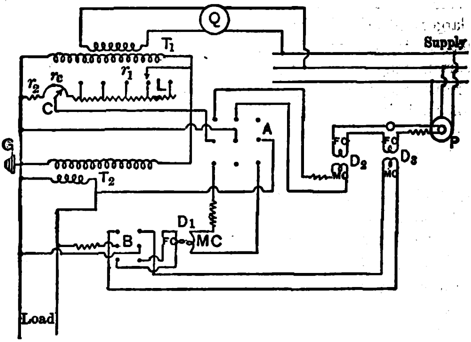

Fig. 10. Connections for Potentiometer Method

sion side of the transformer under test. They consist of non-inductive resistances, containing a non-adjustable portion constituting the greater part of r_2, a middle portion r_c subdivided into equal steps on which a contactor C travels, and a third part constituting the greater part of r_1 on which taps are brought out at points suited to the various voltages to be used in test. One side of the secondary winding is connected to the end of r_2 and the ground G; the other is connected (for ratio test) through switch A, which is in the downward position, through a resistance and the moving element of the dynamometer D_1 to the contactor C. By suitably proportioning the resistances r_1, r_2 and the steps of r_c, the outfit is made direct reading in terms of $\frac{\text{true ratio}}{\text{marked ratio}}$ of the transformer.

Precaution. — Balance can only be secured by a proper connection with regard to polarity of the secondary of the transformer under test to the primary. If the reversed connection is used, double the secondary voltage is applied to the circuit through contactor and dynamometer. A sufficient resistance to protect the dynamometer should therefore be inserted when trying out each transformer to be tested. As soon as an approximate balance is obtained, this resistance may be reduced to secure sensitiveness.

Determination of Ratio. — The fixed coil of the dynamometer D_1 is excited from the low-tension terminals of the transformer under test through the switch B in the downward position. Other secondary load may also be applied to the secondary terminals. With this load and the voltage and frequency suitably adjusted, and with the high-tension lead L connected to the proper tap on r_1, the contactor C is moved until the dynamometer D_1 indicates nearly zero. If the resistance at which the dynamometer indicates zero lies between two steps of the contactor, the nearest may be taken or the readings of dynamometer on both steps may be noted and the result obtained by interpolation. If r_1 and r_2 are respectively the resistances from the contactor C to the high-tension and to the grounded lines, then

$$\text{True ratio} = \frac{r_1 + r_2}{r_2},$$

subject to a small error due to phase angle between primary and secondary voltages, which is negligible for a phase angle of 2 degrees or less, provided

the resistance of the circuit from the contactor C through the dynamometer is approximately equal to r_2.

Determination of Phase Angle. — To obtain the phase angle the switches A and B are thrown upward. The drop of primary voltage across r_2 is thus applied to the potential element of dynamometer D_2, while the secondary voltage is applied to the potential element of dynamometer D_3, both through large non-inductive resistances. The current elements of the dynamometers are placed in series and excited from the phase-shifting transformer P. When the phase of the excitation is shifted so that dynamometer D_2 indicates zero, the phase angle between primary and secondary voltages is

$$\gamma = \sin^{-1}\frac{W}{VA},$$

where W is the watts indicated by the dynamometer D_3, V is the voltage and A the current applied to its potential and current elements respectively.

Speed of Operation. — Ratio points may be taken at the rate of one minute each while operating, and phase-angle points at a somewhat slower rate. Single-point checks can be made practically as rapidly as the transformers can be connected and the voltage, load and frequency adjusted. One observer is required for ratio test, two for phase-angle test.

Standardized Transformer Method for Determining Ratio of Potential Transformer. — The transformer to be tested should be placed in multiple with the standard transformer of the same rated ratio on the high-tension side, and standardized portable voltmeters should be connected to the two secondaries. These should be read, interchanged and read a second time to eliminate errors in calibration of the voltmeters. It is not difficult to maintain an accuracy of about 0.2 per cent on ratio test by this method with carefully standardized apparatus near the rated voltages of the transformer. More accurate determinations of ratio and determinations of phase angle if desired should be made in a thoroughly equipped laboratory, and the check results used simply to verify the unchanged condition of the transformer.

Voltmeter and Resistance Method of Determining Ratio. — Where two transformers of the same rated ratio and a voltmeter with suitable multipliers are available, good checking may be done according to the method shown in Fig. 11. T_1 is a step-up transformer to furnish the voltage for use in test. T_2 and T_3 are potential transformers of similar ratio, T_3 being the transformer under test. V_2 is a portable voltmeter. V_1 is a good portable voltmeter or a laboratory standard instrument. M is a multiplier of such resistance R_m that closing the switch P causes the voltmeter and multiplier to read nearly the same from the primary supply as the voltmeter alone reads from the secondary with the switch S closed. In operation the switch P is closed, and readings made on V_1 and V_2. Then the switch P is opened and S is closed. V_2 is held at the same reading and V_1 is read. If the resistance of V_1 is R_v, its first reading E_1 and its second reading E_2,

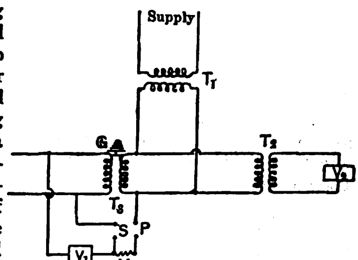

Fig. 11. Connections for Voltmeter and Resistance Method

$$\text{True ratio} = \frac{E_1\,(R_m + R_v)}{E_2 R_v}.$$

If the two readings are close together in the scale of V_1, no specially standardized instrument is necessary. The reading of V_2 does not enter into the result, as it is only used to hold the primary voltage at the same point for the two readings. The accuracy of the method depends on the accuracy of reading of the instruments used, although the absolute values of the readings do not affect it. With care the error should not exceed 0.2 per cent.

Mutual Inductance Method of Determining Phase Angle of Potential Transformer. — The phase angle may be determined by the addition to the ratio-testing outfit described above of a mutual inductance whose primary is placed in series with r_1 or r_2 and whose secondary is in series with the circuit from the contactor C through the dynamometer D_1 in a way similar to that described under current transformers. The primaries of two similar transformers may be placed in multiple, and the difference in their secondary voltages read on a low reading instrument. Where the phase angle is the same in both the transformers, this is an excellent method of comparison if the current drawn in the voltmeter is kept small by the use of a high-resistance instrument.

SPECIFICATIONS. — Heating limits, insulation test, etc., should be in accordance with the Standardization Rules of the A.I.E.E. (q.v.).

Ratio and phase angle under definite conditions of secondary connected load may, for the highest class of product, be defined substantially in accordance with Figs. 1, 2, 5 and 6. Even better accuracy than that shown in these figures can sometimes be secured with considerable increase in cost and amount of material. For less exacting service transformers of lower cost and less accuracy can be procured. The conditions to be fulfilled vary so much that definite general specifications cannot well be given.

For accurate work, especially with current transformers and in cases where much depends on the result, abridged tests covering the performance under operating conditions may be required in connection with each individual transformer. Unless very careful tests are made, however, the information from a curve representing the average of many determinations is apt to be more reliable than the results of one determination.

INSTALLATION.—Instrument transformers previous to installation should be kept in a cool, dry place. All handling should be done in such a manner as to avoid damage to the insulation, particular care being used on those types where the insulation is exposed. Oil-type transformers are usually shipped without oil, and temporary wooden blocking is often placed in the tank. This blocking should be removed before installation. If the transformers have been stored for a considerable time, or if they have been exposed to moisture, they should be thoroughly dried out before installing. (*See Transformers.*) Those of the oil type should be filled with a good quality of dry oil.

Grounding of Transformers.— Both current and potential transformers should be installed in a clean, dry place, preferably at the back of the switchboard in the case of low-voltage transformers, so that all parts, except those that are grounded, will clear all conducting or semi-conducting material by at least twice and preferably by three times the sparking distance of the normal line voltage. The casings and frames should be grounded. The secondary wiring should be grounded at such a point as will not interfere with proper operation of instruments connected to the transformers. See article on *Ground Connections.*

Resistance of Leads. — Secondary leads should be of low resistance and special attention should be given to making all contacts perfect in the wiring connected to the secondary of current transformers. A resistance not exceed-

ing 0.2 ohm (200 feet of No. 10 wire) is usually satisfactory for the secondary circuit of a current transformer operating watt-hour meters or wattmeters. Considerably greater length of leads may be used where ammeters and protective devices only are used because of the lower accuracy required. With potential transformers, the error due to drop in leads is proportional to the amount of current passing through them, which is determined by the number and kind of devices operated. For ordinary circumstances the drop should be less than 0.5 per cent; where special accuracy is desired, the lead resistance should be negligible, or the accuracy test of the transformer should be made with a resistance equivalent to the actual leads placed in series with the testing load. Leads should always be close together, enclosing as little area as possible between them.

Fuses. — Potential transformers should be fused on the primary side. The fuse should be designed to protect the line from disturbance due to failure of the transformer, rather than to protect the transformer against secondary overloads. The fuse should be of such resistance as will not cause appreciable errors in the ratio of transformation.

OPERATION. — After the current transformer has been installed it should need no other care than being kept clean. The secondary of a current transformer must never be left open-circuited. If it becomes desirable to open the secondary winding to insert or remove instruments, the secondary of the current transformer should first be carefully short-circuited. If the secondary has been open even momentarily while current flowed in the primary, the transformer should be demagnetized; see above under *Testing*. Current transformers should always be considered as part of the line circuit and should never be handled except to change connections. Even then only the secondary leads should be touched. When it becomes necessary to change secondary connections the ground connection should be inspected to assure that it is in good condition and is so made that it will not be disconnected in handling the secondary leads. Grounded protective cases should be used where necessary to prevent attendants from coming in accidental contact with current transformers.

Potential transformers should receive the same care in operation as power transformers. No power should be drawn from them except that required for a suitable load of instruments and the usual switchboard devices. The same precautions should be used in handling as with power transformers.

REPAIRS. — In general, replacement or repair by the maker is to be preferred to repairs made by the user where anything more than broken leads or simple external injuries are to be remedied. If repairs to core or windings are attempted, care should be exercised to duplicate as exactly as possible the original construction especially in regard to number of turns and resistance of windings and exact assembly of core. After repairs are completed, the transformer should be carefully tested both for accuracy and for insulation strength.

WEIGHTS, DIMENSIONS AND COSTS. — Current transformers in ordinary use for circuits from 110 to 110,000 volts range from 4 pounds to 1500 pounds weight with oil, and from a maximum dimension of 6 inches to a height of 8 feet with a diameter of 30 inches, depending on the quality of the transformer and the voltage of the circuit on which it is to operate. Potential transformers have nearly the same range of sizes.

The cost of instrument transformers depends on the circuit voltage for which they are designed, and is also affected in the case of current transformers by the ratio of the transformer. There is a considerable range between the prices offered by various manufacturers for transformers of the same rating; the lower prices are, however, associated with less accuracy or with less insulation strength or both.

The approximate cost of an instrument transformer of high grade representing accuracies as per Figs. 1 and 2 for current transformers and Figs. 5 and 6 for potential transformers is as follows:

COST OF POTENTIAL AND CURRENT TRANSFORMERS

Type of Transformer	Voltage of Circuit	Insulation Test Voltage	Price, dollars
Potential	2,200	10,000	25 to 30
"	3,300	10,000	30 to 35
"	4,400	10,000	40 to 50
"	5,500	12,500	50 to 60
"	6,600	15,000	60 to 70
"	11,000	25,000	70 to 80
"	13,200	30,000	
"	22,000	50,000	140 to 150
"	26,400	60,000	
"	33,000	74,000	200 to 220
"	50,000	112,500	400 to 600
"	60,000	135,000	
Current	2,500	10,000	20 to 30
"	15,000	50,000	35 to 45
"	27,000	75,000	90
"	45,000	120,000	125
"	70,000	175,000	250

Current transformers for a 2500-volt circuit with 10,000 volt insulation test and accurate for use with a single instrument or meter, giving a ratio curve approximately like *B* in Fig. 1, cost from $14 to $18.

TRANSIENT ELECTRIC PHENOMENA AND OSCILLATIONS. — (*See also Alternating Currents; Capacity and Charging Current; Electricity and Magnetism, Principles of; Inductance and Inductive Reactance; Transmission Lines.*)

Establishment of a Direct Current in a Coil. — Let E be a constant direct electromotive force, r the resistance of the coil, L the inductance of the coil (assumed constant); then t seconds after closing the circuit (placing the coil and e.m.f. in series) the current in the coil is

$$i = \frac{E}{r}\left(1 - \epsilon^{-ut}\right), \tag{1}$$

where ϵ is the base of the natural logarithms and $u = \frac{r}{L}$. See *Exponential Functions* for values of ϵ^{-x}.

Time Constant of a Coil. — The time required for the exponent $ut = \frac{rt}{L}$ to reach the value unity, and therefore for the current to reach 63.2 per cent of its final value, is called the time constant of the coil, and is equal to $\frac{L}{r}$. The larger the time constant the longer the time required for the current to reach its steady value $\frac{E}{r}$.

Decay of Current in a Coil when Coil is Short-circuited. — Using the same notation as above, the current in the coil t seconds after short-circuiting it is

$$i = I_0 \epsilon^{-ut}$$

where I_0 is the current in it at the instant the short-circuit is made.

Charging a Condenser Through a Resistance from a Source of Constant E.M.F. — Let E be a constant e.m.f., C the capacity of the condenser, r the resistance in series with it, and let the condenser be originally uncharged. Then if the conductance of the condenser and the inductance of the circuit are both negligible, the voltage across the condenser, the current in the circuit and the charge on the condenser t seconds after the circuit is closed (thereby connecting the condenser, resistance and e.m.f. in series), are respectively

$$\left.\begin{aligned} v &= E(1 - \epsilon^{-ut}), \\ i &= \frac{E}{r}\epsilon^{-ut}, \\ q &= CE(1 - \epsilon^{-ut}), \end{aligned}\right\} \tag{2}$$

where $u = \frac{1}{rC}$. For values of ϵ^{-x} see *Exponential Functions.*

Time Constant of a Condenser and Resistance in Series. — The time required for the exponent $ut = \frac{t}{rC}$ to reach the value unity, and therefore for the voltage and charge on the condenser to reach 63.2 per cent of their final values, is called the time constant of this circuit, and is equal to rC. The larger the time constant the longer the time required for the voltage across the condenser to reach the value of the e.m.f. impressed on the circuit.

Discharge of a Condenser Through a Resistance. — Using the same notation as above, and assuming negligible conductance in the condenser and negligible inductance in the circuit, the voltage across the condenser, the current

in the circuit and the charge on the condenser t seconds after short-circuiting it through a resistance r, the condenser being charged to a voltage V_0 at the instant of short-circuit (but no current flowing), are respectively

$$\left.\begin{aligned} v &= V_0 \epsilon^{-ut}, \\ i &= -\frac{V_0}{r}\epsilon^{-ut}, \\ q &= CV_0 \epsilon^{-ut}, \end{aligned}\right\} \tag{3}$$

where $u = \dfrac{1}{rC}$.

GENERAL EQUATIONS FOR LUMPED INDUCTANCE AND CAPACITY. — Let the various quantities be as designated in Fig. 1. The differential equations for this circuit are

$$\left.\begin{aligned} i &= gv + C\frac{dv}{dt}, \\ v &= e - ri - L\frac{di}{dt}, \end{aligned}\right\} \tag{4}$$

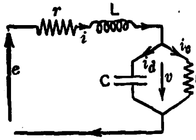

Fig. 1.

where i is the instantaneous current in the impedance coil (equal to the total displacement and conduction current through the condenser), v is the potential drop through the condenser in the direction of the current, and e is the impressed voltage, constant or varying. g represents the "leakance" of the condenser, i.e., the power dissipated in the condenser at any instant is gv^2.

At any given instant, say at $t = 0$, let the impressed e.m.f. be changed from any previous value to a new value $E \sin \theta$, and let this impressed e.m.f. from this instant vary sinusoidally, i.e., at any instant t thereafter, let $e = E \sin (\omega t + \theta)$, where $\omega = 2\pi f$ and f is the frequency of this e.m.f. in cycles per second. (The solution for a constant impressed e.m.f. E can be obtained by putting $f = 0$ and $\theta = \pi/2$ in the equations below.) Let I_0 and V_0 be respectively the values of the current i and of the potential drop v through the condenser at time $t = 0$. I_0 and V_0 may or may not be zero, depending upon the condition of the circuit previous to the change in the impressed e.m.f.

Steady State Relations. — The complete solution of equations (4) shows that the current and voltage at any instant after impressing the e.m.f. on the circuit are each composed of two terms, (1) a term which dies out with time and (2) a term, added to the first, which represents the final or steady (alternating) state of the current and voltage respectively. The "steady state" solution of (4) is readily effected by the ordinary methods of alternating-current calculation (*see Alternating Currents*), and is as follows:

$$\left.\begin{aligned} i_2 &= \frac{E}{Z}\sin(\omega t + \theta - \phi), \\ v_2 &= \frac{E}{yZ}\sin(\omega t + \theta - \phi - \eta), \end{aligned}\right\} \tag{5}$$

where

$$\left.\begin{aligned} Z &= \sqrt{R^2 + X^2} \quad &\text{and} \quad \phi &= \tan^{-1}\frac{X}{R}, \\ R &= r + \frac{g}{g^2 + b^2}, & X &= x - \frac{b}{g^2 + b^2}, \\ b &= \omega C, & x &= \omega L, \\ y &= \sqrt{g^2 + b^2}, & \eta &= \tan^{-1}\frac{b}{g}, \end{aligned}\right\} \tag{6}$$

Free Oscillations. — The transient terms in the complete solution of equations (4) are as follows:

$$\left.\begin{aligned} i_1 &= \epsilon^{-ut}\left[D\cos\omega_0 t - \left(\frac{D'}{\omega_0 L} + \frac{qD}{\omega_0}\right)\sin\omega_0 t\right], \\ v_1 &= \epsilon^{-ut}\left[D'\cos\omega_0 t + \left(\frac{D}{\omega_0 C} + \frac{qD'}{\omega_0}\right)\sin\omega_0 t\right], \end{aligned}\right\} \quad (7)$$

where

$$\left.\begin{aligned} u = \frac{1}{2}\left(\frac{r}{L} + \frac{g}{C}\right) \quad &\text{and} \quad q = \frac{1}{2}\left(\frac{r}{L} - \frac{g}{C}\right), \\ \omega_0 &= \sqrt{\frac{1}{LC} - q^2}\ . \end{aligned}\right\} \quad (8)$$

These three constants, u, q and ω_0 are constants of the circuit, and are independent of the manner in which the transient oscillation is set up. The frequency of this "natural" oscillation is

$$f_0 = \frac{\omega_0}{2\pi} = \frac{1}{2\pi}\sqrt{\frac{1}{LC} - q^2}.$$

When q^2 is small compared with $\frac{1}{LC}$ the natural frequency is $f_0 = \frac{1}{2\pi\sqrt{LC}}$. Due to the resistance of the coil and leakance of the condenser, these natural oscillations die out with time proportionally with ϵ^{-ut}, or the amplitudes of both the transient current and the transient voltage decrease by the fraction ϵ^{-u} each second.

The constants D and D', which determine the amplitudes of the transient terms (equations 7) are given by the following relations:

$$\left.\begin{aligned} D &= I_0 - \frac{E}{Z}\sin(\theta - \phi), \\ D' &= V_0 - \frac{E}{yZ}\sin(\theta - \phi - \eta), \end{aligned}\right\} \quad (9)$$

where I_0 is the current in the coil and V_0 the voltage across the condenser at the instant ($t = 0$) at which any change is made in the circuit conditions, i.e., switch opened or closed, or e.m.f. short circuited.

Solution when Damping is Great. — When q^2 is greater than $1 \div (LC)$, ω_0 becomes imaginary and the oscillation therefore has an imaginary frequency, which means that the transient terms die out without oscillating. Equations (7), (8) and (9) still hold in this case and will give the *real* solution *provided* that in equation (7) "cos" is changed to "cosh" (hyperbolic cosine), and "sin" is changed to "sinh" (hyperbolic sine) and for ω_0 is taken the value $\sqrt{q^2 - \frac{1}{LC}}$. See *Hyperbolic Functions* for tables of "sinh" and "cosh." The expressions for u, q, D and D' remain unaltered.

Critical Damping. — Where $\omega_0 = 0$, that is, when $q^2 = 1 \div (LC)$, equations (7) for the transient current and voltage become

$$\left.\begin{aligned} i_1 &= \left[D\left(1 - qt\right) - \frac{D't}{L}\right]\epsilon^{-ut} \\ v_1 &= \left[\frac{Dt}{C} + D'\left(1 + qt\right)\right]\epsilon^{-ut} \end{aligned}\right\} \quad (10)$$

where D and D' are given by equations (9).

Complete Solution. — The complete expressions for the current and voltage at any instant are in all cases

$$\left.\begin{aligned} i &= i_1 + i_2, \\ v &= v_1 + v_2, \end{aligned}\right\} \qquad (11)$$

where i_2 and v_2 are given by equations (5) and i_1 and v_1 are given by equations (7), the latter changed as noted above when q^2 is greater than $1 \div (LC)$ or reducing to equation (10) when $q^2 = 1 \div (LC)$.

Discharge of a Condenser through an Impedance Coil. — The above equations may be used to obtain the solution of the special case of a condenser charged to a voltage V_0 and short-circuited at time $t = 0$ through a coil having both resistance and inductance. Assume that at time $t = 0$ the current through the condenser is zero. The "steady state" terms in this case are zero, and only the transient terms appear, viz.,

$$\left.\begin{aligned} i &= -\frac{V_0}{\omega_0 L}\epsilon^{-ut}\sin\omega_0 t, \\ v &= V_0\epsilon^{-ut}\left(\cos\omega_0 t + \frac{q}{\omega_0}\sin\omega_0 t\right), \end{aligned}\right\} \qquad (12)$$

where the values of u, q and ω_0 are as given above, equations (8). When $1 \div (LC)$ is greater than q^2, equations (12) apply directly; the current-time curve in this case is shown in Fig. 2. When $1 \div (LC)$ is less than q^2 the circular functions become hyperbolic functions and $\omega_0 = \sqrt{q^2 - \frac{1}{LC}}$ and the current-time curve is as shown in Fig. 3. When $q^2 = 1 \div (LC)$, equations (12) reduce to

$$i = -\frac{V_0}{L}t\epsilon^{-ut} \quad \text{and} \quad v = V_0\epsilon^{-ut}(1 + qt). \qquad (13)$$

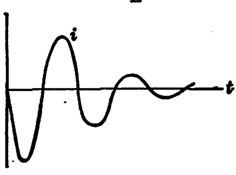

Fig. 2. $q < \frac{1}{\sqrt{LC}}$

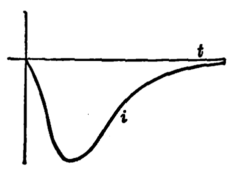

Fig. 3. $q > \frac{1}{\sqrt{LC}}$

OSCILLATIONS IN TRANSMISSION LINES. — Oscillations similar in nature to those discussed above occur in a transmission line when any change takes place in the load connections and particularly when high voltages are suddenly induced in the line by lightning discharges or when heavy currents are suddenly interrupted. The mathematical analysis of such cases is extremely involved, since account must be taken of the distributed nature of the inductance and capacity, and also of the fact that the possible periods of oscillations depend not only upon the line constants but also upon the constants of the apparatus at the two ends of the line. See article on *Transmission Lines*.

[H. PENDER.]

TRANSMISSION LINES. — (*See also Capacity and Charging Current; Conduits and Conduit Lines, Underground; Copper; Corona, Electric; Cross Arms; Distribution Lines; Distribution and Transmission Systems; Inductance and Inductive Reactance; Insulators for Overhead Lines; Insulator Pins; Trolley Systems, Overhead; Wind Pressure; Wires and Cables, Bare; Wires and Cables, Insulated; Wiring of Buildings.*) Circuits designed for transmitting relatively large amounts of power from one fixed point to another are called transmission lines, while those for delivering small amounts at numerous points are called distribution circuits. The same type of construction is used for both kinds of lines when designed for operation at the same voltage. The formulas used in the electrical design of both distribution and transmission lines and in the mechanical design of wire spans are included in this article; see also the articles on *Trolley Systems, Overhead*, for formulas for railway distribution, and *Wiring of Buildings* for formulas for interior wiring. The construction details given in this article refer primarily to three-phase lines designed to operate at or above 13,200 volts; for the construction of low-voltage lines see *Distribution Lines.* For a discussion of the general features of the various types of distribution and transmission systems see the article on *Distribution and Transmission Systems.*

The following is a brief table of contents of this article:

DEFINITIONS AND FUNDAMENTAL RELATIONS. — The following definitions and relations apply to all types of transmission and distribution lines.

Generator End and Load End. — By the generator end of the line is meant the end which is connected to the source of power (either directly or through transformers), and by the load end is meant the end which is connected to the load or substation which is supplied with power over the line.

Per cent Power Loss (Q). — By per cent power loss as used in this article is meant the percentage ratio

$$Q = 100 \cdot \frac{\text{total power lost in the line}}{\text{total power delivered at load end}}. \qquad (1)$$

Hence if P is the power delivered, then the total power supplied to the line and load is

$$P_0 = P\left(\frac{100 + Q}{100}\right). \tag{2}$$

Per cent Voltage Loss (D). — By per cent voltage loss as used in this article is meant the percentage ratio*

$$D = 100 \cdot \frac{\text{(voltage at generator end)} - \text{(voltage at load end)}}{\text{voltage at load end}}. \tag{3}$$

Hence calling E the voltage at the load end, the voltage at the generator end is

$$E_0 = E\left(\frac{100 + D}{100}\right). \tag{4}$$

The per cent voltage loss allowed under various conditions is discussed in detail in the article on *Distribution and Transmission Systems;* the allowable voltage loss is usually between 2 and 20 per cent, the most common figure being 10 per cent.

In the case of a direct-current line with a single load at its far end, the per cent power loss and the per cent voltage loss are always equal, but in the case of an alternating-current line the per cent voltage loss may be either greater or less than the per cent power loss, depending upon the constants of the line and the power factor of the load, or may even be negative, i.e., there may be an actual rise of voltage at the load end above the voltage at the generator end; see below.

Efficiency of Transmission. — By the efficiency of transmission is meant the percentage ratio

$$100 \cdot \frac{\text{power output of line at load end}}{\text{total power input to line at generator end}}. \tag{5}$$

The per cent efficiency is related to the per cent power loss Q as follows:

$$\text{Per cent efficiency} = \frac{10{,}000}{100 + Q}. \tag{6}$$

ELECTRICAL DESIGN OF DIRECT-CURRENT LINES. — Two types of problems arise: (1) given a definite line with known constants, what is the power loss and voltage loss for a given load, and (2) to transmit a given amount of power a given distance with a given allowable loss, what will be the size and weight of the conductor required? In the following paragraphs are given the necessary formulas for the several cases.

Two-wire Line; Concentrated Load at Far End. — Let

E = volts between wires at the load end of the line,

$P = \dfrac{EI}{1000}$ = kilowatts taken by load,

$I = \dfrac{1000\,P}{E}$ = amperes taken by load,

l = length of each line wire in feet,

r = ohms per 1000 feet of conductor; see tables in article on *Wires and Cables, Bare,*

$R = \dfrac{rl}{500}$ = total resistance of line (both conductors), in ohms.

* In the case of an alternating-current line the difference in the numerator of this ratio is the algebraic difference between r.m.s. values of the two voltages, not the vector difference.

The following relations then hold:

$$\text{Total kilowatts lost} = p = \frac{RI^2}{1000} = \frac{rlI^2}{500{,}000} = \frac{2\,rlP^2}{E^2}, \tag{7}$$

$$\text{Total volts lost} = v = RI = \frac{rlI}{500} = \frac{2\,rlP}{E}, \tag{8}$$

$$\text{Per cent power loss} = Q = \frac{100\,p}{P} = \frac{rlI^2}{5000\,P} = \frac{200\,rlP}{E^2}, \tag{9}$$

$$\text{Per cent voltage loss} = D = \frac{100\,v}{E} = \frac{rlI}{5\,E} = \frac{200\,rlP}{E^2}, \tag{10}$$

$$\left.\begin{array}{l}\text{Resistance of each con-}\\ \text{ductor per 1000 feet}\end{array}\right\} = r = \frac{500\,v}{lI} = \frac{QE^2}{200\,lP} = \frac{DE^2}{200\,lP}. \tag{11}$$

Calculation of Size and Weight of Conductor for Concentrated Load. — From the value of r calculated from any one of the relations given in equation (11), the size of wire may be found from the tables in the article on *Wires and Cables, Bare;* the next larger size of wire (next smaller gauge number) should usually be chosen when the calculated resistance lies between that of two commercial sizes. The wire selected must also have sufficient current-carrying capacity; see *Wires and Cables, Bare*; *Wires and Cables, Insulated;* and *Wiring of Buildings*. For outside lines, however, the current-carrying capacity will in general be ample unless the allowable voltage loss is excessive. For an outside overhead line a wire smaller than No. 6 A.W.G. (or B. & S.) gauge is seldom used, chiefly on account of its lack of mechanical strength.

Let w = weight per 1000 feet of the wire finally selected, then

$$\text{Total weight of conductor in pounds} = W = \frac{wl}{500}. \tag{12}$$

Direct Calculation of Total Weight of Conductor (W); Two-wire Line. — For preliminary estimates it is sometimes convenient to calculate the total weight of conductor directly, without reference to a wire table. The total weight of conductor for a two-wire line with concentrated load at its end is given by the formula

$$W = \frac{KP}{Q}\left(\frac{l}{E}\right)^2 \text{ pounds}, \tag{13}$$

where P is the power taken by the load, l the length of the line (length of each wire), E the voltage at the load, Q the per cent power loss (= per cent voltage drop for 2-wire d-c. line) and K a constant depending upon the material of the conductor and the units in which P, l and E are expressed, viz.,

VALUES OF K IN FORMULA 13

Material	E in volts, l in feet, P in kilowatts	E in kilovolts, l in miles, P in kilowatts
Copper (98 per cent conductivity).......	13.5	380
Aluminum (61 per cent conductivity)...	6.5	185
Any material of specific gravity δ having a conductivity of c per cent at 20° C...	$\frac{141\,\delta}{c}$	$\frac{3940\,\delta}{c}$

NOTE. — The values of K given for copper and aluminum are about 5 per cent greater than their theoretical values to allow for stranding, higher working temperature, etc.; 100 per cent conductivity corresponds to 1.724 microhms per centimeter cube at 20° C.

Example: Two-wire D-C. Line, Concentrated Load.—A load of 100 kw. is to be transmitted over a two-wire line to a motor operating at 230 volts, the motor being 1000 feet from the power-house switchboard. For a 10 per cent power loss or voltage drop in the line, the approximate total weight of copper required is, from equation (13),

$$W = \frac{13.5 \times 100}{10}\left(\frac{1000}{230}\right)^2 = 2550 \text{ pounds.}$$

From equation (11) the resistance per 1000 feet is

$$r = \frac{10 \times (230)^2}{200 \times 1000 \times 100} = 0.0264 \text{ ohm per 1000 feet.}$$

The nearest even circular mil size is 400,000 circular mils (stranded), which has a resistance of 0.0270 ohm per 1000 feet at 77° F. (*see Wires and Cables, Bare*), and a weight of 1240 pounds per 1000 feet. From equation (12) the total weight of conductor is then

$$W = \frac{1240 \times 1000}{500} = 2480 \text{ pounds.}$$

This wire, if bare, weather-proofed, or insulated with paper or varnished cambric, will safely carry the required current of 100,000/230 = 435 amperes, but if rubber insulated and mounted indoors, a larger wire should be required, viz., 600,000 circular mils, according to the National Electric Code (*see Wires and Cables, Bare*).

Calculation of Two-wire Direct-current Line in Terms of Voltage at Generator End.—When the volts E_0 at the generator end are given instead of the volts E at the load end, the calculations for a line of given total resistance of R ohms with a concentrated load of P kilowatts at the load end may be made in the same manner as above by first finding the volts E at the load by the formula

$$E = \frac{E_0}{2}\left[1 + \sqrt{1 - \frac{4000\,RP}{E_0^2}}\right]. \tag{14}$$

For an efficiency of transmission of less than 50 per cent, the sign before the radical should be − instead of +, but an efficiency of less than 50 per cent practically never occurs in power transmission. It is of interest to note that for an efficiency of 50 per cent $P = E_0^2 \div (4000\,R)$ which is the maximum power which can be delivered at the far end of the line for a given impressed voltage at the generator end.

When E has been calculated by this formula (14), the formulas (7) to (13) above may be applied directly.

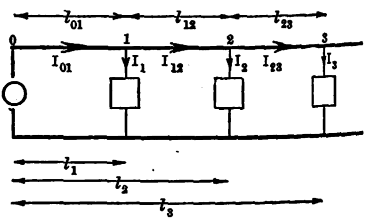

Fig. 1.

Two-wire Line; Distributed Load.—When a line supplies a number of loads at different distances from the generator end, the voltage loss to the far end of the line is the same as would be produced by a load, concentrated at the "center of gravity" of the line and taking a current equal to the total current taken by all the loads. The center of gravity of the line is defined as follows: Let I_1, I_2, I_3, etc., be the currents taken from the line by the various loads, Fig. 1, and let R_1, R_2, R_3, etc., be the total line resistances (both wires) from the generator end to the respective loads, and put

$$I = I_1 + I_2 + I_3 + \ldots \tag{15}$$

Then the center of gravity is that point between which and the generator end of the line the total line resistance is

$$R_g = \frac{R_1I_1 + R_2I_2 + R_3I_3 + \ldots}{I}. \tag{16}$$

When the line conductor has the same cross-section throughout its length, then the center of gravity is at the distance,

$$l_g = \frac{l_1I_1 + l_2I_2 + l_3I_3 + \ldots}{I} \tag{16a}$$

from the generator end, where l_1, l_2, l_3, etc., are the distances of the respective loads from the generator end.

The total voltage loss to the far end of the line is then

$$v = R_gI = \frac{rl_gI}{500}, \tag{17}$$

where the distance l_g is in feet and r is the resistance of the conductor per 1000 feet, the second relation in (17) holding only when the conductor has the same cross-section throughout its length.

The total kilowatts lost in the line are

$$p = \frac{1}{1000}\left(R_{01}I_{01}^2 + R_{12}I_{12}^2 + R_{23}I_{23}^2 + \ldots\right), \tag{18}$$

where, referring to Fig. 1, R_{01} = total resistance (both wires) from 0 to 1, R_{12} = total resistance (both wires) from 1 to 2, etc., and $I_{01} = I_1 + I_2 + I_3 + \ldots$ = the current in the line from 0 to 1, $I_{12} = I_2 + I_3 + \ldots$ = the current in the line from 1 to 2, etc. When the cross-section of the line conductor is the same throughout its length equation (18) may be also written

$$p = \frac{r}{500{,}000}\left(l_{01}I_{01}^2 + l_{12}I_{12}^2 + l_{23}I_{23}^2 + \ldots\right), \tag{18a}$$

where the distances l_{01}, l_{12}, l_{23}, etc., are as shown in Fig. 1, and are measured in feet, and r is the resistance of the line conductor per 1000 feet.

Calculation of Size and Weight of Conductor for Distributed Load. — For a conductor of the same cross-section throughout, the required resistance per 1000 feet for a given voltage loss of v volts to the end of the line may be calculated from the formula

$$r = \frac{500\,v}{l_gI}, \tag{19}$$

where l_g, expressed in feet, and I are given by formulas (16a) and (15). The size and weight of conductor can then be found by reference to the wire tables in the article on *Wires and Cables, Bare.*

When the loads are far apart and the smaller loads are farthest from the generator, it is sometimes advisable to use different sizes of conductors for the various portions of the line. For a given voltage loss v to the end of the line, the minimum weight of conductor is obtained when the volts lost per unit length of conductor in each section of the line is proportional to the square root of the current in this portion of the line. For minimum total weight of conductor then, referring to Fig. 1, the resistance per 1000 feet *of wire* for the section between 1 and 2, say, must be

$$r_{12} = \frac{1}{\sqrt{I_{12}}} \cdot \frac{500\,v}{l_{01}\sqrt{I_{01}} + l_{12}\sqrt{I_{12}} + l_{23}\sqrt{I_{23}} + \ldots}, \tag{20}$$

where the lengths are in feet; and similarly for the other sections. The weight of wire for each section may then be found by reference to the wire tables in the article on *Wires and Cables, Bare,* and the total weight W can then be computed. Vice versa, for a line proportioned in this manner the voltage loss to the end of the line for a given total weight of copper will be a minimum.

A line proportioned in this manner, however, does not give minimum power loss for the total weight of conductor used. For a given total weight of conductor the total power loss will be a minimum when the power loss per unit length of conductor in each section of the line is directly proportional to the current in this section, i.e., when the

voltage loss per unit length in each section is the same, which means that the weight per unit length of each section must be proportional to the line current in this section. Whence letting W be the total weight of the conductor in pounds, then the power loss will be a minimum when the section from 1 to 2, say, has a weight in pounds per 1000 feet of

$$w_{12} = I_{12} \frac{500\,W}{l_{01}I_{01} + l_{12}I_{12} + l_{23}I_{23} + \ldots}, \tag{21}$$

where the lengths are in feet; and similarly for the other sections. The size of wire for each section may be obtained from the wire tables in the article on *Wires and Cables, Bare*. When the sizes as found by the two formulas (20) and (21) differ considerably, the choice will depend upon which is the more important, minimum power loss or minimum voltage loss.

Three-wire Direct-current Line. — When a three-wire circuit is exactly balanced, i.e., when the loads between each of the two outer wires and the neutral are the same and are connected to the neutral at the same point or points, no current flows in the neutral wire. The formulas given above for a two-wire line then apply directly to the case of a balanced three-wire line, noting however that the E (= volts between wires) in these formulas is to be taken as the volts between the *outer* wires, and that the weight as calculated by the above formulas is the weight of the two outer wires. The neutral wire is usually made equal in size to each outer wire, but when only slight unbalancing is expected it is sometimes made smaller. When the neutral is made equal in size to the outer wire the total weight of the three conductors will be 50 per cent more than that given by formula (13), when E in this formula is taken equal to the volts between the outer wires.

The exact calculation of the voltage loss and power loss when the loads on the two sides of the system are different and are connected at different points is somewhat complicated, but can always be effected by the application of Kirchhoff's Laws for an electrical network; see *Electricity and Magnetism, Principles of*.

SIZE AND WEIGHT OF CONDUCTORS FOR ALTERNATING-CURRENT LINES. — As a rough guide in fixing upon a preliminary design, the following facts should be noted; complete formulas for the various calculations required are given later.

1. A power loss of approximately 10 per cent of the delivered power is usually allowed.

2. A line voltage of approximately 1000 volts per mile of line is common practice for long-distance lines not over 150 miles in length; that is, for a 10-mile line a line voltage of 10,000 volts would be employed; for a 100-mile line a line voltage of 100,000 volts would be used. The maximum line voltage at present (1914) employed is 150,000 volts and the maximum distance of transmission is 240 miles.

3. On the basis of 1000 volts per mile of line, unity power factor at the load, a 10 per cent power loss, and copper at 15 cents per pound, the cost of the copper required for a three-phase line is \$4.00 per kilowatt delivered, and for a single-phase or two-phase four-wire line \$5.33 per kilowatt delivered.

Calculation of Total Weight of Conductor for A-C. Lines. — The size and total weight of the conductor required for any conditions * of length, power delivered, power factor, line voltage and power loss may be calculated as follows:

* These formulas are based on the assumption that the charging current is negligible in comparison with the load current, which condition is practically realized in all but the longest high-voltage lines; formulas for power loss taking the charging current into account are given later.

Let

E = voltage between wires at the load end of the line,
P = total power taken by all phases of the load,
$\cos\phi$ = power factor of load, as a decimal,
l = length of line (= length of each line wire),
Q = allowable total power loss in per cent of delivered power.

Then the total weight of all conductors is given by the formula

$$W = \frac{KP}{Q}\left(\frac{l}{E\cos\phi}\right)^2 \quad \text{pounds,} \qquad (22)$$

where K is a constant depending upon the number of phases and wires, the material of the conductor and the units in which the various quantities are expressed, viz.,

VALUES OF K IN FORMULA 22

Material and units	Single-phase or balanced 4-wire 2-phase*	Balanced 3-wire 3-phase
Copper (98 per cent conductivity):		
E in volts, l in feet, P in kilowatts ...	13.5	10
E in kilovolts, l in miles, P in kilowatts	380	285
Aluminum (61 per cent conductivity):		
E in volts, l in feet, P in kilovolts....	6.5	4.9
E in kilovolts, l in miles, P in kilowatts	185	140
Any material of specific gravity δ having a conductivity of c per cent at 20° C.:		
E in volts, l in feet, P in kilowatts....	$\frac{141\,\delta}{c}$	$\frac{106\,\delta}{c}$
E in kilovolts, l in miles, P in kilowatts	$\frac{3940\,\delta}{c}$	$\frac{2950\,\delta}{c}$

NOTE. — The values of K given for copper and aluminum are taken about 5 per cent greater than their theoretical values to allow for stranding, higher working temperatures, etc. 100 per cent conductivity corresponds to 1.724 microhms per centimeter cube at 20° C.

* For a 3-wire 2-phase system with the middle conductor having a cross-section equal to $\sqrt{2}$ times the cross-section of either outer wire multiply these constants by 0.85, taking for E the voltage (volts or kilovolts) between the middle wire and either outer wire.

Calculation of Commercial Size of Conductor and Corresponding Total Weight. — Formula (22) takes no account of the available commercial sizes of wire. These sizes differ successively by approximately 25 per cent in cross-section. The weight can also be determined by calculating the resistance of the required conductor per 1000 feet or per mile, and taking from the wire tables in the article on *Wires and Cables, Bare,* the nearest commercial size. Neglecting the charging current, the required resistance per unit length of wire is

$$r = \frac{K_1 Q\,(E\cos\phi)^2}{lP} \quad \text{ohms,} \qquad (23)$$

where K_1 is a constant depending on the number of phases and wires and the units in which the other quantities are expressed, as given in the table below.

From the wire table the corresponding weight (w) per unit length of conductor having a resistance nearest to that calculated by formula (23) is obtained; the total weight of conductor, including all wires, is then

$$W = K_2wl \qquad \text{pounds,} \tag{24}$$

where K_2 is a constant depending upon the number of phases and wires and the units in which w and l are expressed, as given in the table below.

VALUES OF K_1 AND K_2 IN FORMULAS 23 AND 24

Units	Single-phase	Balanced 4-wire 2-phase*	Balanced 3-wire 3-phase
E in volts, l in feet, P in kilowatts, r in ohms per 1000 feet and w in pounds per 1000 feet.	$K_1 = 0.005$ $K_2 = 0.002$	$K_1 = 0.01$ $K_2 = 0.004$	$K_1 = 0.01$ $K_2 = 0.003$
E in kilovolts, l in miles, P in kilowatts, r in ohms per mile and w in pounds per mile.	$K_1 = 5$ $K_2 = 2$	$K_1 = 10$ $K_2 = 4$	$K_1 = 10$ $K_2 = 3$

* The values of K_1 given in this column when used in formula (23) will give the resistance per 1000 feet or per mile of either outer wire in a 3-wire 2-phase system; the middle wire should, for the same energy loss per pound, have a cross-section 41 per cent greater than either outer, but when commercial sizes (B. & S. gage) are used, either a wire one gage number smaller (25 per cent greater cross-section) or two gage numbers smaller (60 per cent greater cross-section) may be used; in the first case the corresponding value of K_2 is 0.81 times the values given in this column and in the second case 0.90 times the values given in this column.

Current per Wire; Heating of Line Conductors. — The size of wire as determined from formula (23) must be ample to carry the required current without overheating. Heating of the line conductors is seldom a limitation in outside overhead lines, but for inside wiring or underground cables the temperature rise may set a limit to the size of wire which may be used. It is therefore always wise to determine the current which the conductor must carry, and make sure that the wire is sufficiently large not to overheat; see articles on *Wires and Cables, Bare; Wires and Cables, Insulated;* and *Wiring of Buildings,* for tables of current-carrying capacity under various conditions.

The current per line wire in amperes may be calculated from the following formulas, in which E *is the kilovolts* between wires at the load end, P *the total kilowatts* (all phases) delivered to the load, and $\cos\phi$ the power factor of the load as a fraction.

$$\left.\begin{array}{ll} \text{Single-phase:} & I = \dfrac{P}{E\cos\phi}. \\[2ex] \text{Two-phase,* 4-wire, balanced:} & I = \dfrac{P}{2\,E\cos\phi}. \\[2ex] \text{Three-phase, 3-wire, balanced:} & I = \dfrac{P}{\sqrt{3}E\cos\phi}. \end{array}\right\} \tag{25}$$

Example: Calculation of Weight and Size of Conductor for a Three-phase Line. — A load of 20,000 kilowatts is to be transmitted by means

* E is here the volts between the two wires of the same phase. This formula also gives the current in each outer of a balanced 2-phase 3-wire line, E being the kilovolts between either outer and the middle wire; the current in the middle is $\sqrt{2}$ times the current in each outer.

of an overhead three-phase line of copper wire to a substation 50 miles away operating at 60,000 volts between wires, the frequency being 25 cycles per second, and the power factor of the load 80 per cent with the current lagging; a power loss of 10 per cent of the delivered power to be allowed. From formula (22) the required total weight of copper is

$$W = \frac{285 \times 20{,}000}{10}\left(\frac{50}{60 \times 0.8}\right)^2 = 618{,}000 \text{ pounds}.$$

From formula (23) the required resistance per mile of conductor is

$$r = \frac{10 \times 10(60 \times 0.8)^2}{50 \times 20{,}000} = 0.231 \text{ ohm per mile}.$$

The nearest commercial size is 250,000 circular mils (stranded), which has a resistance of 0.228 ohm per mile at 77° F. (*see Wires and Cables, Bare*), and a weight of 4080 pounds per mile. From formula (24) the total weight is then

$$W = 3 \times 4080 \times 50 = 612{,}000 \text{ pounds}.$$

The current corresponding to the given load is, from formula (25),

$$I = \frac{20{,}000}{\sqrt{3} \times 60 \times 0.8} = 241 \text{ amperes},$$

which will give a negligible temperature rise in the wire. See section on *Current-carrying Capacity* in article on *Wires and Cables, Bare*.

Calculation of Size and Weight of Conductors for a Given Per cent Voltage Loss. — The voltage loss in an alternating-current line depends not only upon the resistance of the line, but also upon the line reactance, and in the case of long lines upon the electrostatic capacity of the line. It is therefore impossible to express directly in a simple formula the size or weight of the wire in terms of the voltage loss. The most practical method of making such calculations is to assume first that the per cent power loss is equal to the given per cent voltage loss, and calculate the size by formula (23); then using this size of wire calculate the per cent voltage loss by the formulas given below. If this calculated voltage loss differs appreciably from the given voltage loss, choose the next larger or smaller size of wire (accordingly as the calculated loss is greater or less than the given loss) and recalculate the voltage loss, and so on, until the proper size of wire has been found.

FACTORS WHICH AFFECT THE VOLTAGE AND POWER LOSS IN A-C. LINES. — Due to the inductance and electrostatic capacity the per cent voltage loss in an alternating-current line is not so easily calculated as the voltage loss in a direct-current line and is in general different from the per cent power loss, by an amount dependent upon the inductance and capacity of the line, the frequency and the power factor of the load.

Determination of Line Constants. — The four fundamental line constants are the resistance (r) and inductance (L) of the line conductors per unit length and the capacity (C) and leakage conductance (G) per unit length. For all but the shortest transmission lines the mile is usually the most convenient unit of length, and this unit will be used throughout the remainder of this article unless distinctly stated otherwise. Tables of resistance, inductance and capacity both per mile and per 1000 feet are given respectively in the articles on *Wires and Cables, Bare; Inductance and Inductive Reactance;* and *Capacity and Charging Current.* From the inductance and capacity per mile or per 1000 feet may be calculated for any given frequency the reactance x ($= 2\pi fL$) and the capacity

susceptance* b ($= 2\pi fC$) for the corresponding unit of length. In the last two articles just mentioned are given full tables of reactance and of capacity susceptance per mile for frequencies of 60 and 25 cycles per second; dividing the numerical values given in these tables by 5.28 will give the corresponding quantity per 1000 feet. For any other frequency of f cycles per second, multiply the numerical values given in the tables for 25 cycles by the ratio $f/25$; i.e., for 40 cycles the reactance is 1.6 times the reactance for 25 cycles.

Allowance for Skin Effect in Conductors. — For non-magnetic wires the increase in the conductor resistance due to the so-called skin effect is equal to 2 per cent when the quotient

$$\text{(cycles per sec.)} \div \text{(ohms per mile of conductor)} = 485. \tag{26}$$

For smaller values of this quotient the increase of resistance due to skin effect diminishes very rapidly; see article on *Skin Effect.* The skin effect is therefore practically negligible at 25 cycles for all copper conductors smaller than 1,000,000 circular mils, and at 60 cycles for all copper conductors smaller than 450,000 circular mils. The corresponding limiting sizes for aluminum are about 30 per cent larger. The skin effect is quite appreciable in copper or aluminum cables with a steel core; it is usual to neglect the conductivity of the steel core entirely in calculating the resistance of such cables.

Apparent Resistance and Reactance in Unsymmetrical Arrangements of Wires. — When the three wires of a three-phase line are so arranged that they form the three edges of an equilateral prism the reactance of each wire is the same as for one wire of a two-wire line. However, when the wires are arranged all in one plane, as is frequently done, the unequal mutual induction sets up a reactive electromotive force in each outer wire which is not in quadrature with the current in this wire; see equation (20) in the article on *Inductance and Inductive Reactance.* As a result, both the apparent resistance and the apparent reactance of each outer wire is different from its true resistance and reactance. Let r = the true resistance per mile of each wire in ohms, x = the reactance per mile of each wire in ohms, as given in the tables in the article on *Inductance and Inductive Reactance;* and f = the frequency in cycles per second, then the apparent resistances and reactances per mile of the three wires, No. 2 being the middle wire, are:

$$\left.\begin{array}{lll} r_1 = r + 0.00121f, & r_2 = r, & r_3 = r - 0.00121f, \\ x_1 = x - 0.00070f, & x_2 = x, & x_3 = x - 0.00070f. \end{array}\right\} \tag{27}$$

The changes in the apparent resistances do not indicate any change in the power dissipated as heat in the wires but a transfer of energy from one wire to the other by the magnetic field surrounding the wires. These relations are deduced from equation (20) in the article on *Inductance and Inductive Reactance*, assuming sine-wave currents equal in effective value and differing in phase by exactly 120°. The assumption that the currents are exactly balanced cannot be strictly true, since the inequality in the apparent resistances and reactances of the three wires tends to unbalance the system, but the values just given may be taken as a fair approximation when the voltage loss in the line is not over 10 per cent, say. When the line wires are transposed these mutual inductance effects are eliminated from the line as a whole, though the apparent impedances of the three wires in any one "exposure" of the transposition will be different; the transpositions, however, keep the currents balanced.

Similar effects take place in a two-phase three-wire line, see p. 1671.

Leakage Conductance. — The leakage current, even at very high voltages, is usually negligible in power transmission lines, but for telephone lines, the leakage is much greater, due to the large number of small insulators used, and has a very appreciable effect on both the attenuation and distortion of the voice currents. McMeen (*see article on Telephone Lines*) gives the fol-

* The capacity susceptance to neutral as given in the tables (i.e., in micromhos per mile) is equal to the charging current in amperes per mile per million volts between wire and neutral; the charging current for any other voltage to neutral is in proportion.

lowing values of the leakage conductance of telephone lines, the conductance being from one wire to neutral,

$$\left.\begin{array}{lll} \text{Very dry} & g = 0.004 & \text{micromhos per mile.} \\ \text{Average} & g = 0.08 & \text{micromhos per mile.} \\ \text{Very wet} & g = 1.0 & \text{micromhos per mile.} \end{array}\right\} \quad (28)$$

The leakage conductance from one wire to the other is one-half these values. Note that A megohms per mile equals $1/A$ micromhos per mile.

When the voltage is sufficiently high on a power line to cause the formation of corona (*see article on Corona*), an appreciable leakage current passes from one wire to the other. Even for a sine-wave voltage this leakage current is by no means sinusoidal, since its instantaneous values are practically zero except during the peak of the voltage wave, and consequently the corona loss cannot be accurately represented by a constant leakage conductance. Roughly, however, calling p_c the average value of the corona loss from each wire in watts per mile, corresponding to the given line voltage, the leakage conductance to neutral in micromhos per mile due to the corona may be taken equal to

$$g_c = \frac{p_c}{V^2}, \qquad (29)$$

where V is the effective (r.m.s.) kilovolts to neutral.

Rise of Voltage at Load End of Line on Open Circuit. — In every alternating-current transmission line the voltage at the load end when this end is open is higher than at the generator end, although in short low-frequency lines this rise is inappreciable. In overhead lines for which the product

$$(\text{cycles per sec.}) \times (\text{length of line* in miles}) < 10{,}000, \qquad (30)$$

this no-load rise as a percentage of the delivered voltage is, to a close approximation when the resistance of the wire is less than that of a No. 0 B. & S. copper wire, equal to $\left(\frac{fl}{4000}\right)^2$, where f is the frequency in cycles per second, and l the length of the line in miles. For example, in a 25-cycle line 160 miles long this no-load rise is 1 per cent of the delivered voltage, in a 60-cycle line of the same length the no-load rise in voltage is 5.8 per cent of the delivered voltage. The relation expressed by the above formula under the conditions stated is independent of the value of the delivered voltage and of the size and spacing of the wires, at least for all practical cases.

This rise, which is due to the charging current taken by the line, may be looked upon as present at all loads, but when the load is appreciable the voltage drop, due to the load current, unless leading, more than offsets this voltage rise. A leading current may increase the rise in voltage at the load end as the load comes on.

Use of Synchronous Condensers (or Phase Modifiers) to Maintain Constant Voltage at Load End. — By making the line current at the load end of the line lead the line voltage by the proper phase angle, it is possible to compensate entirely for the change in the load voltage which normally takes place as the load current increases. An overexcited synchronous motor connected in parallel with the load is sometimes used for this purpose, as described in detail in the article on *Motors, Synchronous*. A synchronous motor so used is commonly called a synchronous condenser, since the current taken by it leads the voltage impressed on its terminals. A striking example of the use of synchronous motors for this purpose is in connection with the 150,000-volt, 240-mile

* Length of each conductor.

line from Big Creek, Cal., to Los Angeles, constructed in 1913. Two separate lines are used, the total generator output is 70,000 kilovolt-amperes, and the voltage at the load end is controlled by two 15,000-kilovolt-ampere overexcited synchronous motors.

METHODS OF CALCULATING VOLTAGE AND POWER LOSS IN A-C. LINES.—The absolutely rigorous calculation of an alternating-current line requires that the distributed nature of the inductance and capacity be considered, i.e., that the line be considered as made up of an infinite number of sections such as shown in Fig. 7. However, simpler approximate methods may be employed for nearly all power lines such as are now used, and give results sufficiently accurate for all practical purposes. The accuracy of these approximate methods depends primarily upon the frequency and length of the line; the less the value of the product of these two quantities the simpler is the method which may be employed. Accurate calculation of even a short a-c. line with distributed load can be effected only by rather complicated network equations; see under *Kirchhoff's Laws* in the article on *Alternating Currents*.

Limitations of Approximate Methods of A-C. Line Calculations.—The approximate methods of calculating a-c. lines, in the order of their simplicity, may be designated as (1) the simple impedance method; (2) the single end-condenser method; (3) the middle condenser or "T" method and (4) the split condenser or "π" method; the "π" method is also called the "U" method. For short low-voltage lines, the simple impedance method, which neglects entirely the charging current, is usually sufficiently accurate. The single end-condenser method takes the charging current into account in a manner usually sufficiently accurate for all but the longest high-voltage lines. The "T" and "π" methods are still more accurate, but for exact calculations the rigorous method given on p. 1681ff should be used. In fact, it is always well to check an approximate solution by this exact method.

Fundamental Assumptions on which Formulas Given Below are Based.—All the formulas given below are based on the assumptions of pure sine-wave currents and voltages and a perfectly balanced* system. By using the voltage to neutral instead of the voltage between wires, the formulas are also put in such shape that they may be applied directly to either a single-phase, a two-phase four-wire line or to a three-phase three-wire line, a two-phase four-wire line being considered as two separate single-phase lines. The fundamental idea in this method of treatment is that each line wire is considered as a separate circuit. The return wire shown in the various diagrams is therefore to be considered as having no impedance. This method of treatment of *balanced* polyphase circuits is strictly accurate (*see Alternating Currents*), but when the system is not balanced the circuit must be treated by the more general methods of network calculations; see section on *Kirchhoff's Laws in Symbolic Notation* in the article on *Alternating Currents*. Also, when the voltage and current waves are not sinusoidal, each harmonic must be treated separately as described in the article on *Alternating Currents*. The calculation of a two-phase three-wire line is treated separately, p. 1671.

SIMPLE IMPEDANCE METHOD.—This method is based upon the assumption that the electrostatic capacity of the line may be neglected entirely, and that the line may be considered simply as an impedance in series with the load, this impedance having a resistance equal to the total resistance of the line conductor and a reactance equal to the total inductive reactance of the line

* The meaning of a "balanced" system is fully explained in the article on *Alternating Currents* (q.v.).

conductor. Fig. 2 is a diagram of the circuit, and Fig. 2a is a complete vector diagram of the current and voltage. When the wires are unsymmetrically arranged transpositions are assumed.

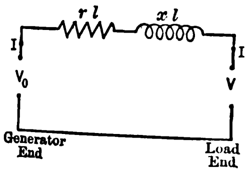

Fig. 2.

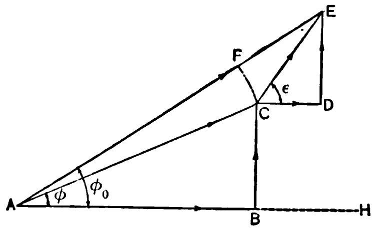

Fig. 2a.

$\overline{AH} = I,\quad \overline{BC} = V \sin\phi,\quad \overline{CE} = zlI,$
$\overline{AC} = V,\quad \overline{CD} = rlI,\quad \overline{AE} = V_0,$
$\overline{AB} = V\cos\phi,\quad \overline{DE} = xlI,\quad \overline{FE} = V_0 - V$

Let V = volts to neutral at load end of the line (= volts between wires divided by 2 in case of a single-phase line, and volts between wires divided by $\sqrt{3}$ in the case of a three-phase line),
I = amperes per wire; see formula (25) above,
l = length of each line wire in miles,
$Z = \dfrac{V}{lI}$ = "equivalent" impedance of the load per mile of line,
$\cos\phi$ = power factor of the load at end of line,
$\sin\phi = \sqrt{1 - \cos^2\phi}$ = the reactive factor of the load; $\sin\phi$ is to be taken positive for a lagging and negative for a leading current,
V_0 = volts to neutral at the generator end of the line,
r = conductor resistance per mile of line in ohms; see tables in article on *Wires and Cables, Bare,*
x = conductor reactance per mile of line, in ohms; see tables in article on *Inductance and Inductive Reactance,*
$z = \sqrt{r^2 + x^2}$ = conductor impedance* per mile of line, in ohms,
Q = per cent power loss, as a percentage of delivered power,
D = per cent voltage loss, as a percentage of delivered voltage.

From the vector diagram it is evident that the voltage at the generator end is

$$V_0 = \sqrt{(V\cos\phi + rlI)^2 + (V\sin\phi + xlI)^2}, \tag{31}$$

* A convenient way of calculating an expression of the form $\sqrt{a^2 + b^2}$ is to write it $a\sqrt{1 + \left(\frac{b}{a}\right)^2}$ or $b\sqrt{1 + \left(\frac{a}{b}\right)^2}$ accordingly as a is greater or less than b; the expression under the radical will then always lie between the numbers 1 and 2, and no difficulty will be experienced with decimal points. When b/a is less than 0.3, then the expression $\sqrt{a^2 + b^2} = a + \dfrac{b^2}{2a}$ with an error of less than 0.1 per cent, and when a/b is less than 0.3, then $\sqrt{a^2 + b^2} = b + \dfrac{a^2}{2b}$ with an error of less than 0.1 per cent. The error in the approximate expressions, diminishes very rapidly as the ratio of b/a or a/b, as the case may be, decreases, being only 0.02 per cent when the ratio is 0.2.

which may also be written

$$V_0 = V\sqrt{\left(\cos\phi + \frac{r}{Z}\right)^2 + \left(\sin\phi + \frac{x}{Z}\right)^2}, \tag{32}$$

where r and x are per mile of line.

The current at the generator end is the same as at the load end.

The per cent power loss is

$$Q = \frac{100\,rlI}{V\cos\phi} = \frac{100\,r}{Z\cos\phi}, \tag{33}$$

and the per cent voltage loss is

$$D = \frac{100\,(V_0 - V)}{V} = 100\left[\sqrt{\left(\cos\phi + \frac{r}{Z}\right)^2 + \left(\sin\phi + \frac{x}{Z}\right)^2} - 1\right]. \tag{34}$$

The power factor at the generator end is

$$\cos\phi_0 = \left(\frac{100 + Q}{100 + D}\right)\cos\phi. \tag{35}$$

Relation between Impedance Drop and Voltage Loss.—The total impedance drop, which is zlI volts, should be carefully distinguished from the voltage loss, which is $v = V_0 - V$ volts. The vector diagram, Fig. 2a, will make the difference clear. For a given impedance drop of, say, A per cent, the voltage at the load end of the line may be anything from A per cent less than the voltage at the generator end to A per cent greater than the voltage at the generator end. The determining factor is the difference between the power-factor angle (ϕ) of the load and the power-factor angle $\left(\epsilon = \tan^{-1}\frac{x}{r}\right)$ of the line; only when $\epsilon - \phi = 0$ are the voltage loss and impedance drop the same. When $\epsilon - \phi$ is greater than 90° (which may occur for a leading current, since ϕ is then negative) the voltage at the load end will in general be higher than at the generator end although the impedance drop in the line may be very large. As a fair approximation, when the impedance drop is less than 20 per cent, that is, when z/Z is less than 0.2, the percentage voltage loss may be written

$$D = \frac{100\,z}{Z}\cos(\epsilon - \phi), \tag{36}$$

z and Z being the impedances of the line and load respectively, and ϵ and ϕ the power-factor angles of the line and load respectively.

Example of Calculation by Simple Impedance Method.—Take the case of a three-phase, 60-cycle line 50 miles long, the wires being No. 0000 A.W.G. (or B. & S.) stranded copper spaced symmetrically with 6 feet between centers, and let the load be 15,000 kilowatts at 60,000 volts between wires and at a power factor of 80 per cent with lagging current. The voltage to neutral is then $60{,}000 \div \sqrt{3} = 34{,}600$ and the current per wire $15{,}000 \div (\sqrt{3} \times 60 \times 0.8) = 180$ amperes. The resistance of each wire per mile is 0.269 ohm at 77° F., and the reactance 0.728 ohm. The equivalent impedance of the load per mile of line is $Z = 34{,}600 \div (50 \times 180) = 3.84$. $\cos\phi = 0.8$ and $\sin\phi = \sqrt{1 - \overline{0.8}^2} = 0.6$. Whence

$$\text{Per cent power loss} = Q = \frac{100 \times 0.269}{3.84 \times 0.8} = 8.76 \text{ per cent},$$

$$\text{Per cent voltage loss} = D = 100\left[\sqrt{\left(0.8 + \frac{0.269}{3.84}\right)^2 + \left(0.6 + \frac{0.728}{3.84}\right)^2} - 1\right] = 17.5\%,$$

$$\text{Power factor at generator end} = \cos\phi_0 = \left(\frac{100+8.76}{100+17.5}\right)\times 0.80 = 74.1 \text{ per cent,}$$

$$\text{Per cent impedance drop} = \frac{100\sqrt{0.269^2+0.728^2}}{3.84} = 20.2 \text{ per cent.}$$

Graphical Determination of Voltage Loss; Mershon's Chart (Fig. 3). — The voltage loss may also be determined by means of the chart shown in Fig. 3, which was devised by R. D. Mershon. This chart is nothing more than a means of solving equation (32) graphically. To use the chart calculate

$$\text{the per cent resistance drop} = r\left(\frac{100\, lI}{V}\right), \qquad (37)$$

$$\text{the per cent reactance drop} = x\left(\frac{100\, lI}{V}\right), \qquad (38)$$

and from the point on the curve marked "0" where this curve cuts the vertical line corresponding to the load power factor lay off horizontally the per cent resistance drop, and from the end of this horizontal line lay off vertically upward the per cent reactance drop; the per cent voltage loss is then given by the number on the circle through the end of this vertical line.

Taking the same example as given in the preceding section, $(100\, lI) \div V = (100 \times 50 \times 180) \div 34{,}600 = 26.0$, whence the per cent resistance drop is $0.269 \times 26.0 = 7.0$ per cent and the per cent reactance drop is $0.728 \times 26.0 = 18.9$ and therefore from the chart the per cent voltage loss is 17.6 per cent.

Calculations in Terms of Voltage at Generator End. — When the volts to neutral V_0 at the generator end are given instead of the volts to neutral V at the load end, the calculations for a line of total resistance of R ohms per wire, and total reactance of X ohms per wire for a load of P kilowatts per wire* at a power factor of $\cos\phi$ at the load end may be made in the same manner as above by first finding V by the formula,

$$V = A\sqrt{1 \pm \sqrt{1 - \frac{(R^2+X^2)\,P^2 \times 10^6}{A^4\cos^2\phi}}}, \qquad (39)$$

where

$$A = V_0\sqrt{\frac{1}{2} - \frac{1000\,P\,(R\cos\phi + X\sin\phi)}{V_0^2\cos\phi}}. \qquad (40)$$

The plus or minus sign in the formula for V arises from the fact that for a given amount of delivered power and given voltage at the generator end two different voltages at the load end are possible; for an inductive load the voltage corresponding to the minus sign will in general be less than 50 per cent of the voltage at the generator end, and the "minus sign" solution is therefore usually of no practical importance. The maximum power which can be delivered at the load end for a given voltage at the generator end is

$$P_m = \frac{V_0\cos\phi}{2000\,(\sqrt{R^2+X^2} + R\cos\phi + X\sin\phi)}. \qquad (41)$$

Voltage and Power Loss in Two-phase Three-wire Line. — Take the usual case of the three wires in the same plane, with the common wire midway between the two outers. Let r be the resistance per mile of each outer, and r_1 the resistance per mile of the common wire, taken from the tables in the article on *Wires and Cables, Bare*, and x and x_1 the corresponding reactances per mile taken from the tables in the article on *Inductance and Inductive Reactance*, for a spacing equal to the distance between the middle wire and each outer. Let E be the voltage between each outer and the middle wire, I the amperes in each outer, $\cos\phi$ the power factor of the load, and l the length of the line. Assuming a balanced load, then the voltage between the two outers is $\sqrt{2}\,E$ and the current in the middle wire is $\sqrt{2}\,I$, and the total power delivered to the load is $(2\,EI\cos\phi) \div 1000$ kilowatts. The per cent power loss is then

$$Q = \frac{100\,(r + r_1)\,lI}{E\cos\phi}.$$

* Calling P_t the total kilowatts delivered to the load, then $P = P_t/2$ for a single-phase line, $P = P_t/3$ for a three-phase line and $P = P_t/4$ for a two-phase four-wire line,

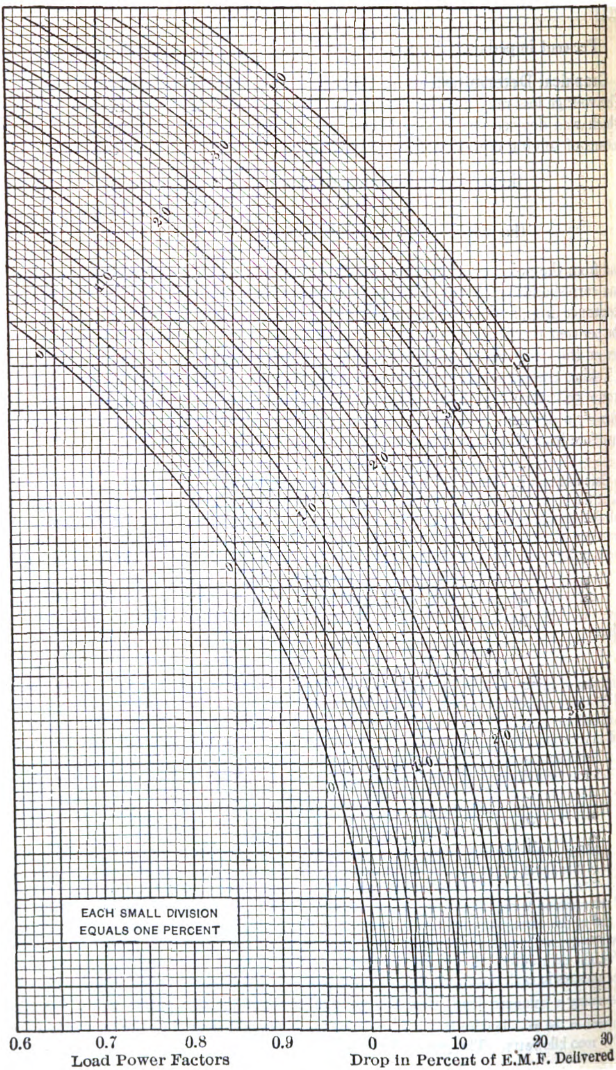

Fig. 3. Mershon's Chart for Calculating Drop in A-C. Line

The equivalent resistances and reactances of the line for the two phases, assuming the currents in the two outer wires to be exactly equal in effective value and to differ in phase by exactly 90°, are

$$R_1 = (r + r_1 - x_1 + 0.0014f)\,l, \qquad X_1 = (x + x_1 + r_1)\,l,$$
$$R_2 = (r + r_1 + x_1 - 0.0014f)\,l, \qquad X_2 = (x + x_1 - r_1)\,l,$$

where f is the frequency in cycles per second. When the wires are transposed only the term $0.0014\,f$ in the expressions for R_1 and R_2 go out, the other terms in the R's and X's remaining unaltered. The voltages at the generator end for the two phases are then

$$E_1 = E\sqrt{\left(\cos\phi + \frac{R_1 I}{E}\right)^2 + \left(\sin\phi + \frac{X_1 I}{E}\right)^2},$$
$$E_2 = E\sqrt{\left(\cos\phi + \frac{R_2 I}{E}\right)^2 + \left(\sin\phi + \frac{X_2 I}{E}\right)^2}.$$

Of course, if the voltages E_1 and E_2 are maintained equal at the generator end, which is usually the case, the assumptions of equal currents and equal voltages at the load end are incorrect, but the above formulas may be used to obtain an approximate value of the voltage loss in the two phases. The unbalancing due to the unequal equivalent impedances of the two phases renders the two-phase three-wire system undesirable except for lines in which the voltage loss is a small percentage of the voltage at the load, and the unbalancing therefore small.

SINGLE END-CONDENSER METHOD. — This method assumes that the total current at the load end is equal to the actual load current plus (vectorially) the charging current which would be taken by a single condenser shunted across the line at the load end, the capacity of this condenser being taken equal to the total capacity of the line. This method gives too low a voltage at the generator end by approximately the same amount that the straight impedance

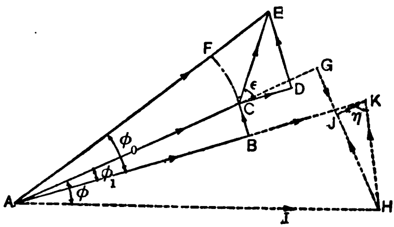

Fig. 4a.

$\overline{AB} = V\cos\phi_1,$
$\overline{BC} = V\sin\phi_1,$
$\overline{CD} = rlI_1,$
$\overline{DE} = xlI_1,$
$\overline{CE} = zlI_1,$
$\overline{AE} = V_0,$
$\overline{FE} = v,$

method gives it too high, and also gives the power loss too low by approximately the same amount that the straight impedance method gives it too high. By averaging the losses obtained by the two methods a close approximation to their true values is obtained.

Fig. 4 is a diagram of the circuit and Fig. 4a is a complete vector diagram of the voltage and current; voltages are shown by full lines and currents by dotted lines. The diagrams and formulas are for the general case of a line with leakage, but for nearly all practical cases the leakage may be neglected.

The effect of the electrostatic capacity of the line is to change both the numerical value and the phase angle of the line current. Or, the condenser and the load may be looked upon as forming together an equivalent load taking a current I_1 at a power factor $\cos\phi_1$ differing from the actual current and power factor of the load. Let

V = volts to neutral at the load end of the line,
I = actual amperes per wire at the load end,
$\cos\phi$ = actual power factor at the load end,
$\sin\phi = \sqrt{1-\cos^2\phi}$ = actual reactive factor at the load end,
l = length of each line wire in miles,
b = capacity susceptance to neutral per mile of line, in micromhos, see tables in the article on *Capacity and Charging Current*,
g = leakage conductance to neutral per mile of line in micromhos, usually taken equal to zero in power lines, as explained above,
$y = \sqrt{g^2+b^2}$ = dielectric admittance to neutral per mile of conductor, in micromhos. Note that for no leakage $y = b$.

The total leakage current, total charging current and total exciting current of the line are then respectively

$$I_g = glV \times 10^{-6}, \qquad I_c = blV \times 10^{-6}, \qquad I_e = \sqrt{I_g^2 + I_c^2}. \tag{42}$$

The total line current, i.e., the resultant of the actual load current and the exciting current, is

$$I_1 = I\sqrt{\left(\cos\phi + \frac{I_g}{I}\right)^2 + \left(\sin\phi - \frac{I_c}{I}\right)^2}. \tag{43}$$

On the assumptions of this method of calculation I_1 is also the current at the generator end.

The power factor of the equivalent load formed by the actual load and the condenser is then

$$\cos\phi_1 = \frac{I\cos\phi + I_g}{I_1}, \tag{44}$$

and the reactance factor of this equivalent load is

$$\sin\phi_1 = \frac{I\sin\phi - I_c}{I_1}. \tag{45}$$

The formulas given above for the straight impedance method are then directly applicable, using for I, $\cos\phi$ and $\sin\phi$ in those formulas the values of I_1, $\cos\phi_1$, and $\sin\phi_1$ just calculated; i.e., the straight impedance method is to be applied not to the actual load but to the equivalent load formed by the actual load and a condenser having an admittance equal to the total admittance of the line.

Example of Calculation by Single End-Condenser Method. — Three-phase line, 50 miles long, No. 0000 A.W.G. stranded copper, 6 feet between centers, frequency 60 cycles, load 15,000 kilowatts, 60,000 volts between wires at load end, 80 per cent power factor at load. This is the same example as used above for the straight impedance method. Then $V = 34{,}600$, $I = 180$, $\cos\phi = 0.8$, $\sin\phi = 0.6$, $l = 50$, $b = 6.03$, $g = 0$, $r = 0.269$, $x = 0.728$. Then,

$$\text{Charging current} = I_c = 6.03 \times 50 \times 34{,}600 \times 10^{-6} = 10.4 \text{ amperes},$$

$$\text{Resultant current} = I_1 = 180\sqrt{(0.8)^2 + \left(0.6 - \frac{10.4}{180}\right)^2} = 174 \text{ amperes},$$

$$\text{Power factor of equivalent load} = \cos\phi_1 = \frac{180 \times 0.8}{174} = 0.828.$$

$$\text{Reactive factor of equivalent load} = \sin\phi_1 = \frac{180 \times 0.6 - 10.4}{174} = 0.561,$$

$$\text{Impedance of equivalent load per mile of line} = Z_1 = \frac{34{,}600}{50 \times 174} = 3.98,$$

$$\text{Per cent power loss} = Q = \frac{100 \times 0.269}{3.98 \times 0.828} = 8.16 \text{ per cent},$$

Per cent voltage loss $= D$

$$= 100\left[\sqrt{\left(0.828 + \frac{0.269}{3.98}\right)^2 + \left(0.561 + \frac{0.728}{3.98}\right)^2} - 1\right] = 16.30 \text{ per cent},$$

$$\text{Power factor at generator end} = \cos\phi_0 = \left(\frac{100 + 8.16}{100 + 16.3}\right) \times 0.822 = 76.4 \text{ per cent.}$$

The per cent power loss and voltage loss obtained by the straight impedance method neglecting the line capacity are respectively 8.76 and 17.6 per cent. As noted above the single end-condenser method gives these losses too low (for inductive loads) by approximately the same amount that the straight impedance method gives them too high, whence closer approximations to the true losses are: per cent power loss = $(8.16 + 8.76) \div 2 = 8.46$ and per cent voltage loss = $(16.3 + 17.6) \div 2 = 17.0$.

Calculation of Effect of Synchronous Condenser. — Formulas (43) to (45) apply directly to the calculation of the effect of a synchronous condenser at the end of the line taking a current having an in-phase or energy component equal to I_g and a quadrature leading component equal to I_c. Fig. 4a then represents the vector relations of the currents and voltages, the vector JK being the in-phase component of the current taken by the synchronous condenser and HJ the quadrature component.

MIDDLE-CONDENSER OR "T" METHOD. — This method assumes that the line may be considered equivalent to the circuit shown in Fig. 5, which represents a single condenser, having a capacity and leakage conductance equal respectively to the total capacity and leakage conductance of the line, shunted across the line at its middle point, the resistance and inductance on each side of this condenser being equal respectively to half the total conductor resistance and inductance.

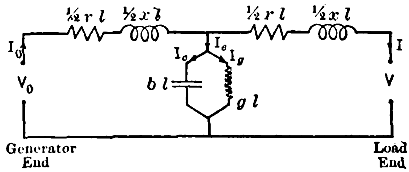

Fig. 5.

An inspection of Fig. 5 will show that the half of the line nearest the load is represented by a straight impedance in series with the load. Hence the voltage, current and power factor at the middle point of the line may be figured by the straight impedance method given above. Then, considering the voltage, current and power factor thus calculated as forming a load at the middle point of the line, the second half of the line may be calculated by the single end-condenser method just described.

By assigning proper values (which are somewhat complicated functions of the actual line constants and the frequency) to the constants of the "T" circuit shown in Fig. 5, this circuit may be made *exactly equivalent*, as far as the relations between the voltage, current and power at the two ends are concerned, *to a line of any length and for any frequency;* the "corrected" constants are entirely independent of the voltage, current and power taken by the load; see p. 1683.

Solution of the "T" Circuit in Symbolic Notation. — The solution of the circuit shown in Fig. 5 is also given below in terms of complex quantities (*see under Symbolic Notation in the article on Alternating Currents*). Let

V = numerical value of volts to neutral at the load end of the line,
I = amperes per wire at the load end of the line, taken as the vector of reference,
$\cos\phi$ = power factor at the load end of the line,
$V = V\cos\phi + jV\sin\phi$ = volts to neutral at the load end of the line, referred to the current at the load end,
$z = r + jx$ = conductor impedance in ohms per mile of wire, r being the resistance per mile and x the reactance per mile,
$y = g + jb$ = dielectric admittance, one wire to neutral, in micromhos per mile of line, where g is the leakage conductance per mile and b the capacity susceptance per mile,
l = length of each wire in miles.

Put

$$M = 10^{-6}yzl^2 = [(gr - bx) + j(br + gx)]\,10^{-6}l^2. \tag{46}$$

Then the current at the generator end, in symbolic notation, is

$$I_0 = (1 + \tfrac{1}{2}M)\,I + 10^{-6}ylV, \tag{47}$$

and the volts to neutral at the generator end, in symbolic notation, are

$$V_0 = (1 + \tfrac{1}{2}M)\,V + zl\,(1 + \tfrac{1}{4}M)I. \tag{48}$$

Calling I_0' and I_0'' the real and "j" components respectively of the current I_0, and V_0' and V_0'' the real and "j" components of the voltage V_0, then the numerical values of the current and voltage at the generator end are

$$I_0 = \sqrt{(I_0')^2 + (I_0'')^2}, \quad \text{and} \quad V_0 = \sqrt{(V_0')^2 + (V_0'')^2}, \tag{49}$$

and the power input per wire at the generator end is

$$P_0 = V_0'I_0' + V_0''\,I_0''. \tag{50}$$

In applying this last formula particular attention must be paid to the signs of the quantities involved, e.g., if $V_0 = 1000 + j\,300$ and $I_0 = 100 - j\,20$, then $V_0' = 1000$, $V_0'' = 300$, $I_0' = 100$ and $I_0'' = -20$, and $P_0 = 1000 \times 100 - 300 \times 20$. The power factor at the generator end is

$$\cos\phi_0 = \frac{P_0}{V_0 I_0}. \tag{51}$$

SPLIT-CONDENSER OR "π" OR "U" METHOD. — This method assumes that the line may be considered equivalent to the circuit shown in Fig. 6, which represents a single impedance in series with the load, the resistance and inductance of this impedance being equal respectively to the total conductor resistance and inductance of the line, and a condenser shunted across the line at each end, each condenser having a capacity and leakage conductance equal respectively to half the total capacity and half the total leakage conductance of the line.

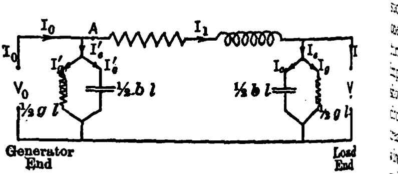

Fig. 6.

An inspection of Fig. 6 will show that the calculation of the line up to the point A at which the condenser at the generator end is connected is exactly the same as for the single end-condenser method described above, except that the capacity and leakage of the end condenser are taken respectively as half the total capacity and half the total leakage of the line. The voltage at the point A is the same as the voltage at the generator end, but to find the current I_0 at the generator end the exciting current I_e' of the condenser shunted across the line at the generator end must be added (vectorially) to the current I_1 at A. Using the same notation as in the section above on the single end-condenser method, the total generator current is then

$$I_0 = I_1\sqrt{\left(\cos\phi_0 + \frac{I_g'}{I_1}\right)^2 + \left(\sin\phi_0 - \frac{I_e'}{I_1}\right)^2},$$

where

$$I_g' = \tfrac{1}{2}glV_0 \times 10^{-6} \quad \text{and} \quad I_e' = \tfrac{1}{2}blV_0 \times 10^{-6}.$$

As in the case of the "T" circuit, a "π" circuit, such as shown in Fig. 6, may be given such "corrected" constants as will make it exactly equivalent for any one frequency, as far as the terminal conditions are concerned, to a line of any length whatever no matter how high this frequency may be; see p. 1683.

Solution of the "π" Circuit in Symbolic Notation. — Using the same notation as in the section above on the *Solution of the "T" Circuit in Symbolic Notation,* and calculating the quantity $\dot{M}$ by the same formula, viz., equation (46), the current and voltage at the generator end in symbolic notation are respectively

$$\dot{I}_0 = (1 + \tfrac{1}{2}\dot{M})\,\dot{I} + 10^{-6}\,\dot{y}l\,(1 + \tfrac{1}{4}\dot{M})\,\dot{V}, \qquad (52)$$

$$\dot{V}_0 = (1 + \tfrac{1}{2}\dot{M})\,\dot{V} + \dot{z}l\dot{I}. \qquad (53)$$

The numerical values of these quantities, the power and the power factor are then to be calculated in the same manner as for the "T" circuit, viz., by formulas (49) to (51).

EXACT CALCULATION OF A-C. LINES OF ANY LENGTH AND FREQUENCY.* — The charging current (and also the leakage current) for any element of a transmission line passes through only that portion of the line conductor between the given element and the generator end. The exact determination of the line current, voltage and power at any point therefore requires that this fact be taken into account; in other words the capacity and leakage of the line are distributed and not lumped as assumed in the above methods of calculation. In Fig. 7 are shown three successive elements of one wire of a line, a return or neutral of zero impedance being also shown to complete the circuit. This method of treating separately each wire of a line is fully explained above, p. 1668.

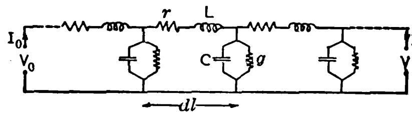

Fig. 7.

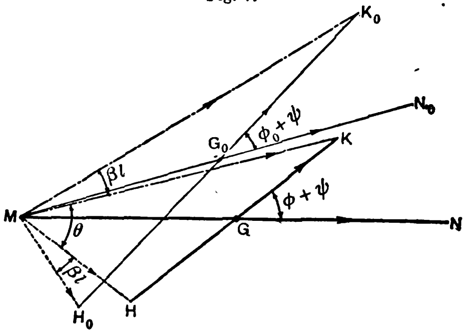

Fig. 7a.

$\overline{MN} = I$, $\quad \overline{MK_0} = A\epsilon^{\alpha l}$,

$\overline{HK} = YV$, $\quad \overline{MH_0} = B\epsilon^{-\alpha l}$,

$\overline{MK} = A$, $\quad \overline{MN_0} = I_0$,

$\overline{MH} = B$, $\quad \overline{H_0K_0} = YV_0$.

In order to make clear the physical meaning of the various terms employed, the general solution is first given in terms of instantaneous values. Following this are given the working formulas (1) in terms of exponentials, viz., ϵ^{x} and ϵ^{-x}, (2) in terms of real hyperbolic functions, and (3) in terms of hyperbolic functions of complex angles.

General Equations of Transmission Line. — Let l = the distance in miles of any point along a transmission line, measured from any arbitrarily chosen point (say from the load end); let i = the instantaneous current in amperes in the conductor at this point, taken positive in the direction *opposite* to that in which l is measured (i.e., positive when *toward* the load end); let v = the potential drop in volts between this point and the neutral; and let r = the conductor resistance in ohms per mile, L = the inductance of the conductor in henries per mile, C = the capacity to neutral in microfarads per mile

* This section is abstracted from the lecture notes of Dr. H. Pender.

and g = the leakage conductance to neutral in micromhos per mile. The following relations then hold at any point along the line, t being time in seconds measured from any arbitrarily chosen instant:

$$\frac{dv}{dl} = ri + L\frac{di}{dt}, \tag{54}$$

$$10^6\frac{di}{dl} = gv + C\frac{dv}{dt}. \tag{55}$$

If the circuit is composed of two or more sections of different constants (e.g., an overhead section and an underground section, or a circuit formed by a step-up transformer, transmission line and a step-down transformer) then a similar set of equations holds for each section of the circuit, the constants r, L, g, and C being in general different for the several sections.

The complete solution of any two equations of the form given by (54) and (55) consists of an infinite series of terms for both v and i, corresponding terms in the two series having the following values:

$$i = \sqrt{2}\,\epsilon^{-(u-s)t}\left[A\epsilon^{\alpha l}\sin(\omega t + \beta l + \theta_1) + B\epsilon^{-\alpha l}\sin(\omega t - \beta l + \theta_2)\right], \tag{56}$$

$$v = \frac{\sqrt{2}}{Y}\epsilon^{-(u-s)t}\left[A\epsilon^{\alpha l}\sin(\omega t + \beta l + \theta_1 - \psi) - B\epsilon^{-\alpha l}\sin(\omega t - \beta l + \theta_2 - \psi)\right]. \tag{57}$$

Physical Interpretation and Names Given to the Various Constants.—The constant ω in equations (56) and (57) is equal to $2\pi f$, where f is the frequency of the oscillation represented by these equations. In the most general case any change in the circuit conditions, such as closing or opening a switch, or a lightning stroke in the vicinity of the circuit, may set up an infinite number of oscillations of different frequencies, their frequency being determined by the initial conditions at the instant the change is made. The current and voltage set up by each oscillation is represented by a set of terms of the form given by (56) and (57), and the resultant current and voltage will be respectively the sum of all the current terms and the sum of all the voltage terms. The oscillation of any given frequency, however, may be considered separately, as it is uninfluenced by the presence of the other oscillations. Moreover, in the case of a composite circuit, consisting say of a step-up transformer, transmission line and step-down transformer, if an oscillation of frequency f is set up in one part of the circuit it will also appear in all other sections of the circuit, though it may be greatly damped in these sections and therefore produce no appreciable effect.

Attenuation Constant (α), Wave Length Constant (β), Wave Length (λ) and Velocity of Propagation (U).—Referring to equations (56) and (57) each oscillation sets up in each section of the circuit two waves, each of which has a wave length $\lambda = \frac{2\pi}{\beta}$; the constant β is therefore called the "wave length constant;" it is a function of the frequency and of the constants r, L, g and C of the circuit. The two waves travel along the line in opposite directions each with a velocity $U = \frac{\omega}{\beta}$; in a composite circuit this velocity U is in general different for each section of the circuit. One wave may be looked upon as the "incident" and the other as the "reflected" wave. The amplitude of each wave diminishes by the factor ϵ^{α} as the wave travels unit distance; the factor ϵ^{α} is called the "attenuation factor" and the constant α is called the "attenuation constant." The attenuation constant is a function of the frequency and the constants r, L, g and C of the circuit; see p. 1680.

Surge Admittance (Y) and its Power-factor Angle (ψ).—The constant Y, which is equal to the quotient of the amplitude (or r.m.s. value) of the incident current wave by the incident voltage wave, is called the "surge admittance" and its reciprocal is called the "surge impedance"; it is a function of the frequency and the constants r, L, g and C of the circuit; see p. 1680. The constant ψ, which is equal to the angle by which the incident current wave leads the incident voltage wave, is called the "power-factor angle of the surge admittance"; it is a function of the frequency and the constants r, L, g and C; see p. 1680.

Amplitude Constants (A and B) and Phase-Angle Constants (θ_1 and θ_2).—The constants are equal to the amplitudes of the incident and reflected current waves at the point from which the distance l is measured, and the constants θ_1 and θ_2 give the

phase of these two waves at this point ($l = 0$) at the instant from which time is measured ($t = 0$). Note that the incident current wave at $l = 0$ leads the reflected current wave by the angle $\theta = \theta_1 - \theta_2$. The determination of these constants for steady state conditions is given on p. 1681.

Natural Damping Constant (u), Energy Transfer Constant (s) and Composite Damping Constant ($u - s$). — In the general case of a natural oscillation in a composite circuit the amplitude of each wave diminishes in unit time by the factor $\epsilon^{(u-s)}$; this factor is called the "composite damping factor," and the constant $(u - s)$ is called the "composite damping constant." The composite damping constant, like the frequency f, is the same for all sections of a composite circuit. In the case of a line of uniform constants throughout, not connected to any terminal apparatus, it can readily be shown that $s = 0$, in which case the amplitude of the oscillations diminishes in unit time by the factor ϵ^{u}; this factor is therefore called the "natural damping factor" and the constant u, which for a section having the constants r, L, g and C per unit length, is equal to

$$u = \frac{1}{2}\left(\frac{r}{L} + \frac{g}{C}\right), \tag{58}$$

is called the "natural damping constant." Any section of a composite circuit for which the actual damping $\epsilon^{(u-s)}$ is less than the natural damping ϵ^{u} must receive energy from some other section; consequently a positive value of s for a given section means that energy is transferred into this section from some other section of the circuit. Similarly, a negative value of s for a given section means that energy is transferred from this section to some other section. The constant s may therefore be called the "energy transfer constant." Since the voltage and current in the circuit cannot increase indefinitely the energy transfer constant s can never have a positive value greater than u.

Since the composite damping constant $(u - s)$ is the same for all sections of a circuit, it follows that the transfer of energy from one section to another by oscillations in a composite circuit will always be into the section in which u is the larger from the section in which u is the smaller. Neglecting the leakage conductance g, this means that energy will be transferred into section 1 from section 2, when $\frac{r_1}{L_1}$ is greater than $\frac{r_2}{L_2}$, that is, energy is transferred from the section of the larger "time constant" $\left(\frac{L_2}{r_2}\right)$ to that of the smaller "time constant" $\left(\frac{L_1}{r_1}\right)$. When the resistances are small, this means that in the limiting case all the energy ($= \frac{1}{2} L_2 I^2$) of the magnetic field of the second section may go into electrostatic energy ($= \frac{1}{2} C_1 V^2$) in the first section, producing therefore a very high voltage at the junction point when the inductance L_2 of the second section is large compared with the capacity C_1 of the first section. This accounts for the very high voltages sometimes set up during switching operations at the junction point of an overhead line with an underground line, or in a transformer connected to a long overhead line.

"Steady State" Conditions in a Transmission Line. — From the above discussion it is evident that when a sufficient time (usually a small fraction of a second) has elapsed after any change in the circuit conditions, the only terms left in the general equations of a transmission line for a given impressed sine-wave voltage of frequency f are those for which $s = u$, viz.,*

$$i = \sqrt{2}\left[A\epsilon^{\alpha l} \sin(\omega t + \beta l) + B\epsilon^{-\alpha l} \sin(\omega t - \beta l - \theta)\right], \tag{59}$$

$$v = \frac{\sqrt{2}}{Y}\left[A\epsilon^{\alpha l} \sin(\omega t + Bl - \psi) - B\epsilon^{-\alpha l} \sin(\omega t - \beta l - \theta - \psi)\right]. \tag{60}$$

The effective value of the current at any point is then equal to the sum of two vectors having the lengths $A\epsilon^{\alpha l}$ and $B\epsilon^{-\alpha l}$, the former leading the latter by the angle $(2\beta l + \beta)$, and the effective value of the voltage is equal to the difference of these same two vectors divided by Y. The phase angle between the voltage and current is equal to the phase angle between the sum and difference of the A and B vectors less the angle ψ.

* For steady state conditions time may be counted from any arbitrarily chosen interval, i.e., θ_1 in equations (56) and (57) may be put equal to zero, and for convenience $-\theta$ may be used for θ_2.

Notation for Steady State Conditions. — These relations are clearly shown in the vector diagram, Fig. 7a, which is a complete vector diagram of a transmission line with distributed capacity and leakage. The four constants α, β, Y and ψ are constants of the line, independent of the load, and are expressed in terms of the ordinary line constants as follows: Let

f = frequency in cycles per second,

r = conductor resistance per mile, in ohms; see tables in article on *Wires and Cables, Bare,*

$x = 2\pi fL$ = conductor reactance per mile, in ohms, corresponding to the impressed frequency f; see tables in article on *Inductance and Inductive Reactance,*

$z = \sqrt{r^2 + x^2}$ = conductor impedance per mile, in ohms,

g = leakage conductance to neutral per mile of line, in micromhos; see above, p. 1667. For power lines g is usually taken equal to zero,

$b = 2\pi fC$ = capacity susceptance to neutral per mile of line, in micromhos, corresponding to the impressed frequency f; see tables in article on *Capacity and Charging Current,*

$y = \sqrt{g^2 + b^2}$ = dielectric admittance per mile, in micromhos; when $g = 0$, then $y = b$,

$\alpha = 10^{-3}\sqrt{\dfrac{yz - bx + gr}{2}}$ = the attenuation constant; for r and g small compared with x and b this reduces to $\dfrac{10^{-3}}{2}\left(r\sqrt{\dfrac{C}{L}} + g\sqrt{\dfrac{L}{C}}\right)$,

$\beta = 10^{-3}\sqrt{\dfrac{yz + bx - gr}{2}}$ = the wave length constant; for r and g small respectively compared with x and b this reduces to $2\pi f \times 10^{-3}\sqrt{LC}$, which for an overhead line equals approximately $\dfrac{2\pi f}{180{,}000}$,

$Y = 10^{-3}\sqrt{\dfrac{y}{z}}$ = surge admittance; for r and g small respectively compared with x and b, this reduces to $10^{-3}\sqrt{\dfrac{C}{L}}$. The reciprocal of the surge admittance is called the "surge impedance,"

$\psi = \tan^{-1}\sqrt{\dfrac{yz - bx - rg}{yz + bx + rg}}$ = the power-factor angle of the surge admittance, taken positive for $gx < br$ and negative for $gx > br$. For r and g small compared with x and b, then $\psi = 28.7\left(\dfrac{r}{x} - \dfrac{g}{b}\right)$ degrees,

$U = \dfrac{2\pi f}{\beta}$ = velocity of propagation in miles per second; for a frequency f sufficiently high to make r negligible compared with x, and g negligible compared with b, this reduces to $\dfrac{10^3}{\sqrt{LC}}$, which for an overhead line with wires far apart is equal to the velocity of light in air, viz., 180,000 miles per second, approximately,

$\lambda = \dfrac{2\pi}{\beta} = \dfrac{U}{f}$ = wave length of each wave in miles; for a frequency f sufficiently high to make r negligible compared with x, and g negligible

compared with b, this reduces to $\frac{10^3}{f\sqrt{LC}}$, which for an overhead line is equal approximately to $\frac{180{,}000}{f}$ miles.*

In the vector diagram and in the formulas given below, let

l = length of the line in miles,

I = effective (r.m.s.) value of the amperes per wire at the load end,

V = effective (r.m.s.) value of the volts to neutral at the load end,

ϕ = the power-factor angle at the load end, i.e., $\cos\phi$ is the power factor at the load end. ϕ is taken positive for a lagging and negative for a leading current,

I_0, V_0, ϕ_0 = corresponding quantities at the generator end.

Solution by Vector Diagram (Fig. 7a). — Having calculated the constants α, β, Y and ψ, and knowing the current I, voltage V and power-factor angle ϕ of the load,

Lay off $\overline{MN} = I$ as the base line, and bisect it at G,

At the angle $(\phi + \psi)$ ahead of $\overline{MN}$ lay off the line $\overline{HK}$ equal in length to YV, so that it is also bisected by G,

Then measure off $\overline{MK} = A$ and $\overline{MH} = B$,

Lay off at the angle $57.3\,\beta l$ degrees ahead of A the line $\overline{MK_0}$ equal in length† to $A\epsilon^{\alpha l}$,

Lay off at the angle $57.3\,\beta l$ degrees behind B the line $\overline{MH_0}$ equal in length to $B\epsilon^{-\alpha l}$.

Then the line $\overline{MN_0} = 2\,\overline{MG_0}$ is equal to the current at the generator end,

The line $\overline{H_0K_0}$ divided by Y is equal to the voltage at the generator end,

The angle between $\overline{G_0N_0}$ and $\overline{G_0K_0}$ less the angle ψ is the power-factor angle at the generator end.

Note that the voltage at the load end if drawn in the diagram would be at the angle ψ behind the vector $\overline{GK}$, and at the generator end would be at the angle ψ behind $\overline{G_0K_0}$.

Algebraic Solution for Steady-state Conditions. —The vector diagram may be solved algebraically as follows: Calculate first the constants A, B and θ from the formulas:

$$A = \tfrac{1}{2}\sqrt{I^2 + (YV)^2 + 2\,YVI\cos(\phi + \psi)}, \tag{61}$$

$$B = \tfrac{1}{2}\sqrt{I^2 + (YV)^2 - 2\,YVI\cos(\phi + \psi)}, \tag{62}$$

$$\theta = \tan^{-1}\left[\frac{2\,YVI\sin(\phi + \psi)}{I^2 - (YV)^2}\right]. \tag{63}$$

Note that $\sin\theta$ has the same algebraic sign as the numerator of this fraction and $\cos\theta$ has the same algebraic sign as the denominator of this fraction; this fixes the quadrant in which θ lies.

Put

$$A_0 = A\epsilon^{\alpha l}, \quad \text{and} \quad B_0 = B\epsilon^{-\alpha l}. \tag{64}$$

* The above formulas for z, y, α, β, Y, ψ, U and λ also hold for the transient or free oscillations in a single circuit, and also for each section of a composite circuit, provided in these formulas $r_1 = r\,(u - s)\,L$ is substituted for r and $g_1 = g + (u - s)\,C$ is substituted for g.

† See the table in the article on *Exponential Functions* for values of ϵ^x and ϵ^{-x}, where x is any number.

The current, voltage and power-factor angle at the generator end are, then, expressing all angles in degrees,

$$I_0 = \sqrt{A_0^2 + B_0^2 + 2\,AB\cos(114.6\,\beta l + \theta)}, \tag{65}$$

$$V_0 = \frac{1}{Y}\sqrt{A_0^2 + B_0^2 - 2\,AB\cos(114.6\,\beta l + \theta)}, \tag{66}$$

$$\phi_0 = \tan^{-1}\left[\frac{2\,AB\sin(114.6\,\beta l + \theta)}{A_0^2 - B_0^2}\right] - \psi. \tag{67}$$

Note that the quadrant in which $(\phi_0 + \psi)$ lies is determined by the algebraic signs of the numerator and denominator of the fraction in the brackets, just as in the case of the angle θ.

Solution of Steady State Conditions in Terms of Hyperbolic Functions.* — The above expressions for the current, voltage and power factor at the generator may also be put in the form,

$$I_0 = I\sqrt{\frac{\cosh(2\,\alpha l + \gamma) + \cos(114.6\,\beta l + \theta)}{\cosh\gamma + \cos\theta}}, \tag{68}$$

$$V_0 = V\sqrt{\frac{\cosh(2\,\alpha l + \gamma) - \cos(114.6\,\beta l + \theta)}{\cosh\gamma - \cos\theta}}, \tag{69}$$

$$\phi_0 = \tan^{-1}\left[\frac{\sin(114.6\,\beta l + \theta)}{\sinh(2\,\alpha l + \gamma)}\right] - \psi, \tag{70}$$

where θ and γ are given by the formulas

$$\gamma = \tanh^{-1}\left[\frac{2\,YVI\cos(\phi + \psi)}{I^2 + (YV)^2}\right], \tag{71}$$

$$\theta = \tan^{-1}\left[\frac{2\,YVI\sin(\phi + \psi)}{I^2 - (YV)^2}\right]. \tag{72}$$

The other quantities are as above defined. Note that θ is the same angle as given by equation (63) and the quadrant in which it lies is to be determined as described in the note under (63). Also note that the constant γ given by (71) may be expressed in terms of A and B, given by (61) and (64), by means of the formula

$$\gamma = \log_\epsilon\left(\frac{A}{B}\right) = 2.302\log_{10}\left(\frac{A}{B}\right). \tag{73}$$

Formulas for Open Circuit and Short Circuit at Load End. — When the line is open at the load end, $I = 0$, whence from equations (61) to (63), $A = \frac{1}{2}\,YV$, $B = \frac{1}{2}\,YV$, and $\theta = 180°$ (since the denominator of the fraction is negative). When the line is short-circuited at the load end, $V = 0$, and $A = \frac{1}{2}\,I$, $B = \frac{1}{2}\,I$, and $\theta = 0°$ (since the denominator of the fraction is positive). The current, voltage and power-factor angle at any point along the line may then be found in either case by substituting these values in equations (65) to (67) which reduce to the simple hyperbolic forms:

On open circuit	On short circuit
$I_0 = YV\sqrt{\sinh^2(\alpha l) + \sin^2(57.3\,\beta l)}$	$I_0 = I\sqrt{1 + \sinh^2(\alpha l) - \sin^2(57.3\,\beta l)}$
$V_0 = V\sqrt{1 + \sinh^2(\alpha l) - \sin^2(57.3\,\beta l)}$	$V_0 = \frac{I}{Y}\sqrt{\sinh^2(\alpha l) + \sin^2(57.3\,\beta l)}$
$\phi_0 = -\tan^{-1}\left[\frac{\sin(114.6\,\beta l)}{\sinh(2\,\alpha l)}\right] - \psi$	$\phi_0 = +\tan^{-1}\left[\frac{\sin(114.6\,\beta l)}{\sinh(2\,\alpha l)}\right] - \psi$

* Tables of hyperbolic functions are given in the article on *Hyperbolic Functions.*

Solution of Steady-state Equations in Complex Hyperbolic Functions.* — Expressing all quantities other than the length l in symbolic notation (*see Alternating Currents*), the equations of the transmission line for *steady state conditions only*, may be written

$$\dot{I}_0 = \dot{I}\,\frac{\sinh\,(l\sqrt{\dot{y}\dot{z}} + \dot{B})}{\sinh \dot{B}}, \tag{74}$$

$$\dot{V}_0 = \dot{V}\,\frac{\cosh\,(l\sqrt{\dot{y}\dot{z}} + \dot{B})}{\cosh \dot{B}}, \tag{75}$$

where the symbols other than B have the same meanings as above, except that they are all expressed as complex quantities and

$$\dot{B} = \tanh^{-1}\left(\frac{\dot{V}}{\dot{I}}\sqrt{\frac{\dot{y}}{\dot{z}}}\right). \tag{76}$$

The real part of $\sqrt{\dot{y}\dot{z}}$ is the attenuation constant and the imaginary or "j" part is the wave length constant.

Rigorously Equivalent "T" and "π" Circuits. — As noted above the middle condenser or "T" circuit, Fig. 5, or the split condenser or "π" circuit, Fig. 6, is rigorously equivalent to the actual transmission line when proper values are assigned to the constants of these circuits. The corrected values z' and y' of the impedance per mile and of the admittance per mile are, in symbolic notation, as follows:

"T" circuit	"π" circuit
$\dot{z}' = \dot{z}\,\dfrac{\tanh\left(\dfrac{l\sqrt{\dot{y}\dot{z}}}{2}\right)}{\dfrac{l\sqrt{\dot{y}\dot{z}}}{2}}$ $\dot{y}' = \dot{y}\,\dfrac{\sinh\,(l\sqrt{\dot{y}\dot{z}})}{l\sqrt{\dot{y}\dot{z}}}$	$\dot{z}' = \dot{z}\,\dfrac{\sinh\,(l\sqrt{\dot{y}\dot{z}})}{l\sqrt{\dot{y}\dot{z}}}$ $\dot{y}' = \dot{y}\,\dfrac{\tanh\left(\dfrac{l\sqrt{\dot{y}\dot{z}}}{2}\right)}{\dfrac{l\sqrt{\dot{y}\dot{z}}}{2}}$

In Dr. Kennelly's tables above referred to are given tables of these correction fractions.

FACTORS AFFECTING THE MECHANICAL DESIGN. — In designing a transmission line the following factors, in addition to the line losses, must be considered: (1) right-of-way, (2) telephone circuits, (3) ground wires, (4) clearances, (5) type of supporting structure, (6) type of insulators, (7) conductors, (8) temperature range, (9) collection of ice, (10) wind velocity and wind pressure. The requirements imposed by these several conditions are noted below in the order mentioned; this is followed by the formulas and curves necessary to make the required calculations.

Location and Width of Right-of-way. — The right-of-way should be as short and as straight as practicable. Its width for a single line should be equal to the width of space over which the conductors normally hang, plus twice the side swing of conductors under maximum wind, plus twice the safe clearance from conductor to possible buildings adjacent to the right-of-way. In computing the side swing allowance must be made for swing of suspension insulators. Side swing of conductor should be based on the longest span ordinarily

* Complete tables and charts of such functions have recently been published by Prof. A. E. Kennelly, *Tables of Complex Hyperbolic and Circular Functions*, Harvard University Press, 1914.

used, and extra width should be secured wherever extraordinarily long spans are made. For telephone lines on separate poles extra width will be required unless the power wires are high enough to swing safely over them. Where two power lines are on one right-of-way the towers for the two lines should be located directly opposite each other, especially on long spans, since the two lines may then be placed close together with less danger of the wires of the two lines swinging together. However, it is usually desirable to have the lines far enough apart so that the towers of one line may fall without striking those of the other line. The right-of-way should be passable (or at least accessible) for patrolling as well as for construction.

When it is necessary that the right-of-way cross railroads, roads or other lines the length of crossing should be reduced to a minimum by making the crossing at as near right angles as practicable. Rights-of-way through swamps often require expensive road building and expensive tower foundations, though small swamps (up to about 1000 feet across) can often be crossed in a single span. Steep side hills require extra expense for foundations and tower extensions, and introduce a hazard of injury to tower from sliding earth, rocks, trees or snow. A right-of-way through forests requires expensive clearing.

It is usually advantageous to own and fence the right-of-way. However, when the right-of-way passes through farm lands, it is sometimes advantageous not to fence it in, but to have it cultivated and kept free from brush. Instead of purchasing a right-of-way, it is often sufficient to obtain easements covering the location of towers and suspension of wires. Easements should include the right to remove and trim trees under and adjacent to the line.

Telephone Circuits for Power Lines. — When the line voltage does not exceed 66,000 volts, the telephone circuits are usually carried on the same poles or towers as the power circuits, being placed below the power conductors. A separate line of wooden poles on the same right-of-way is usually employed when the voltage is higher than 66,000.

Where the telephone wires are on the same supporting structure as the power wires, sufficient clearance between the power and telephone circuits must be allowed to make the telephone line accessible for repairs and also to prevent the two circuits touching under abnormal conditions. On wood pole lines of short span (100 to 125 feet) the vertical clearance at the poles or towers ranges from 4 feet for 22,000 volts to 6 feet for 66,000 volts. On long span lines greater spacing is necessary to allow for safe clearance in the middle of the longest span due to the change in the sag of the power and telephone wires under all conditions of unequal ice loading and all variations of side deflection due to wind.

Telephone wires are ordinarily of copper, though copper-clad steel is sometimes used for long spans. For spans up to 125 feet No. 10 B. & S. copper may be used (though No. 8 is preferable) while for longer spans larger sizes (usually No. 8 or No. 6 or even No. 4) are necessary to allow for sleet load. A spacing of 12 inches between wires may be used for 125-foot spans, but a wider spacing is necessary for longer spans. Where inadequate spacing is used the telephone lines will frequently become crossed by the wind, unless they are strung with little sag, in which case they are overloaded and broken by sleet. With wide spacing and large sag higher poles must be used.

Ground Wires. — Grounded cables or wires are placed above the transmission line circuits to protect the latter from lightning discharges (*see Lightning Protectors*). They are usually grounded at each supporting structure except where short spans are used. The same care must be exercised to obtain clearances between conductors and ground cables or wires, as outlined above under telephone circuits. For tower lines having flexible towers and single-circuit towers having conductors arranged in a horizontal plane, two ground cables are

preferable, but for double-circuit tower lines either one or two may be used. As a general rule a line drawn through the ground cable and any conductor should not make an angle of more than 45 degrees with the vertical.

Clearances. — The following clearances require determination: conductor to ground; to edge of right-of-way; to tower; to ground wire; to telephone wire; to other conductors.

The minimum clearance from the high-voltage wires to the surface of the ground is ordinarily 20 feet or more, and from the telephone wires on towers used for high-voltage wires is 18 feet to ground. The minimum clearance from the wires to the edge of the right-of-way or to the tower, under maximum swing of insulators and cables in the wind, should exceed the striking distance corresponding to the arc-over voltage of the insulators used. The minimum clearance between conductors, under extreme conditions of unequal ice loading (*see below*), should exceed the striking distance of the normal voltage by a factor of safety of at least two. The normal clearance between conductors should be much greater than this, and is ordinarily from 10 inches to 1 foot per 10,000 volts between wires.

Type of Supporting Structure. — (*See also Poles for Overhead Lines; Cross Arms; Towers.*) Wood poles are usually the cheapest form of supporting structure for lines up to about 66,000 volts. Most lines of voltage over 66,000 and some lines of lower voltage are supported on steel towers.

A single line of poles or towers may support one, two and occasionally more circuits. Where several circuits are required two or more single-circuit tower lines with conductors arranged in a horizontal plane have the advantage that the effects of an accident will usually be confined to one circuit, and that one circuit may safely be repaired with another circuit alive, but this arrangement requires the maximum width of right-of-way. Where it is important to use the right-of-way economically two-circuit towers having the conductors of each circuit arranged in vertical planes on each side of the tower are used.

Wood poles are ordinarily placed from 100 to 200 feet apart and steel towers from 400 to 800 feet apart. The span for steel tower lines is ordinarily chosen so as to render the sum of the costs of all of the items a minimum, and is usually found to lie within the limits mentioned.

The poles or towers ordinarily used where the line is straight are designed to resist the weight of the conductors with sleet and the side pressure of wind on them, but not to resist the tension in the conductors which is assumed to be wholly or partially balanced. Such towers are called standard, straight line or suspension towers. Heavier towers designed to resist the unbalanced tension of all of the cables (which may occur if the cables are broken on the other side of the tower), called anchor or dead-end towers, are used at intervals of from five to ten spans where the line is straight. Heavier towers designed to resist the unbalanced lateral resultant of the tension in the cables are also used at angles and are known as angle towers. For economy in design and manufacture anchor and angle towers (for any angle up to about 60°) are usually made interchangeable. Where towers are not very high, economy is often secured by using flexible towers intermediate between square anchor and angle towers. On wood pole lines extra strong poles guyed or braced in all four directions, with double cross arms and double pins and insulators, are used for anchoring the line and at angles.

Type of Insulators. — (*See also Insulators.*) Pin insulators are usually used for voltages up to 50,000 and suspension insulators for higher voltages. Suspension insulators are sometimes used for lower voltage where a high factor of safety is desired. For the lower voltages the cost of the line is usually less for pin than for suspension insulators. The suspension insulator requires a higher tower

than the pin insulator, for the conductor is below the cross arm, and a longer cross arm is also required to allow for the swing of the insulators in the wind.

Conductors for Overhead Lines. — (*See also Wires and Cables.*) Copper, aluminum or steel, or combinations of the two former with steel, are used for line conductors. The use of an all-steel conductor is limited to those cases where great mechanical strength is required, although some economy is claimed for it when high voltages are used and a conductor of large diameter is required on account of corona (*see Corona*). Conductors consisting of a steel center with copper or aluminum outside are used where long spans are desirable and mechanical strength of conductor is required, and may also be used where large diameter is required to prevent corona formation. The maximum stress in wires and cables should not exceed the elastic limit. This condition is ordinarily met if a factor of safety of two, based on the ultimate strength, is used.

Distribution of Stress in Stranded Conductors. — Conductors for long spans are usually stranded when larger than No. 6 B. & S. gage, on account of the tendency to crystallize at the points of support, due to swinging in the wind. However, the maximum size of solid conductor which may be used is dependent largely upon the kind of support; if these are designed to prevent sharp bending, solid conductors, larger than No. 6, may be used. One difficulty in the use of a stranded cable is that for a given total tension in the cable the wires in the various layers are not all stressed equally. In particular, the center wire or core, if of metal, takes more than its share of the tension. On this account the actual sag in the cable when suspended may differ from that calculated, unless an allowance is made for the unequal tension in the various wires composing the cable. One method of avoiding this difficulty is to stress the cable, before stringing it, to a tension per square inch corresponding to the elastic limit of the component wires; the center wire will then be given a permanent set and when the cable is again stressed each of the component wires will tend to take the same proportion of the total tension.

Cables having centers or cores of a different material than the outside strands should be so designed that both materials are stressed to their elastic limit at the same time at the particular temperature at which maximum stress of conductors will occur. The two materials should also share the stress over the operating range of temperatures, to such extent as is possible.

The distribution of stress among the wires of which conductors may be composed applies more particularly to long spans where clearances are important and it is necessary to use small deflections compared to lengths of spans. For all ordinary construction, having spans of 500 to 600 feet or less, a very slight change in either thickness of ice or amount of wind pressure on the conductor will affect results as much as the error resulting from not taking into consideration the distribution of stresses in conductors.

Mechanical Characteristics of Conductor Materials. — For purposes of design both elastic limit and modulus of elasticity of cables should be obtained from tests on samples of the cables actually to be used, since errors in these materially affect the accuracy of the calculations of deflections in spans. The modulus of elasticity of cables varies widely with the number of wires and their pitch or lay in the different layers. Table I shows the values of these quantities and also of the other mechanical properties of conductors commonly used in design, when specific test results are not available. See also the articles on *Aluminum; Copper; Strength and Elasticity; Wires and Cables, Bare.*

Temperature Range. — The maximum and minimum air temperatures which have occurred in any locality for a period of years can be obtained from the records of the United States Weather Bureau, or from similar records for other countries. The minimum air temperature recorded (which may be as

TABLE I

MECHANICAL CHARACTERISTICS OF WIRES AND CABLES

Item	Copper	Aluminum	Steel
Ultimate strength, in lb. per sq. in.	60,000–65,000	25,000–50,000	60,000–80,000
Elastic limit, in lb. per sq. in.	30,000–35,000	11,000–14,000	35,000–40,000
Modulus of elasticity, in pound-inch units	12×10^6–16×10^6	$7\times10^6-10\times10^6$	22×10^6–28×10^6
Coefficient of linear expansion per ° F.	9.6×10^{-6}	12.8×10^{-6}	6.6×10^{-6}
Weight in pounds of a 1-ft. length having a cross section of 1,000,000 circ. mils (stranded)	3.09	0.92	2.67

low as − 40° F. in some of the northern states) will be the minimum temperature which the conductor may be expected to reach. However, since the conductors are exposed to the direct rays of the sun, they will reach a maximum temperature in the summer considerably in excess of the Weather Bureau records, which give the temperatures in the shade.

Another important temperature which should be determined is that of the wire when coated with ice. As noted below, a sleet storm is usually followed by a fall in temperature, and although the ice forms at 32° F., the wire may reach a much lower temperature while the ice is on it.

The following temperature ranges have been used in the design of certain lines:

	Maximum	Minimum
Eastern Canada	+ 120° F.	− 40° F.
Mississippi Valley	+ 120° F.	− 20° F.
Southern California	+ 140° F.	+ 10° F.

Collection of Ice on Wires. — Investigation of the records of the Weather Bureau leads to the conclusion that sleet and ice storms are generally followed by falling temperatures and high winds, and transmission lines should be designed to meet these conditions. Records indicate that under favorable conditions ice and sleet will collect on wires and cables to the same amount in any climate where freezing temperatures are obtained. Mild, moderate and cold climates differ in the frequency with which conditions are favorable. In general, sleet storms are most frequent in the moderate climates, since precipitation takes place more often at freezing temperatures. Destructive sleet storms occur in the eastern part of the United States at least as far south as Atlanta. One-half inch thickness of solid ice on wires and cables is generally assumed in designing transmission lines, but thicknesses of one-quarter and three-quarter inch are also assumed in the more favorable and unfavorable localities.

Ice and sleet generally collect quite uniformly on wires throughout their length. The collection is sometimes in the form of icicles but more often is egg-shaped in cross section, with the wire in the small end of the section. It frequently falls off non-uniformly in sections.

Clear solid ice weighs 57 pounds per cubic foot or 0.033 pound per cubic inch, but sleet or frozen snow such as often collects on wires weighs much less, sometimes as little as 8 pounds per cubic foot.

Effect of Surface and Electric Potential on Collection of Ice.— Local observations of single ice or sleet storms have shown that ice will sometimes collect on one wire or cable and not on an adjoining one. This has led to the conclusion that ice will not collect on certain kinds of wires, but more extensive observations indicate that ice will collect on any kind of wire under favorable conditions. Observations on wires carrying sufficient current to heat them and wires having potential near the critical corona voltage are not sufficiently extensive to warrant the conclusion that they will not collect ice and sleet.

Wind Velocity and Wind Pressure on Wires. — As noted in the article on *Wind Pressure*, the records of the United States Weather Bureau give nominal average velocities for five minute intervals, the true average velocities differing from the recorded velocities as follows:

Recorded velocity in miles per hour	10	20	30	40	50	60	70	80	90	100
Actual velocity in miles per hour	9.6	17.8	25.7	33.3	40.8	48.0	55.2	62.2	69.2	76.2

The Weather Bureau records give no indication of the "gust" velocities which may occur during the five minute periods, and which may greatly exceed the average velocity. Tests with a Dines pressure tube anemometer have shown that the extreme maximum is about 50 per cent greater than the average for short periods.

The extreme maximum wind velocity observed in Chicago in the whole thirty-six year period from 1873 to 1910 was 84 miles per hour (uncorrected) in February, 1894. A velocity of 76 miles per hour (uncorrected) was observed once in November, 1898, and a velocity of 72 miles per hour (uncorrected) was observed seven times. During the ten year period from 1894 to 1903 the maximum wind velocity in a few other representative localities was as follows, all velocities being the observed or uncorrected velocities: Bismark, N. D., 72; Eastport, Me., 78; Buffalo, N. Y., 90; New York City, N. Y., 78; Galveston, Tex., 84; Savannah, Ga., 76; Salt Lake City, Utah, 60. All the maxima range between 60 miles and 90 miles per hour.

The wind pressure on a cable is usually calculated from the formula

$$p = KV^2, \tag{1}$$

where p is the pressure in pounds per square foot of the projected area of the cable (including sleet and insulation, if any), and V is the actual velocity of the wind in miles per hour blowing perpendicularly across the span. The projected area, in square feet, of a one-foot length of cable is equal to the over-all diameter in inches divided by 12, where by over-all diameter is meant the diameter over the ice and insulation, if any. Buck's formula (*see article on Wind Pressure*) gives a value of 0.0025 for the constant K, whereas a value of 0.002 derived from the work of the Weather Bureau and experiments of Borda is also used.

Maximum Loading. — There is considerable difference of opinion as to what should be taken as the maximum loading in designing a transmission line. The Committee on Overhead Line Construction of the N.E.L.A. have proposed three different loadings, viz.: (A) No ice and a wind pressure of 15 pounds per square foot; (B) ice ½-inch thick and a wind pressure of 8 pounds per square foot; and (C) ice ¾-inch thick and a wind pressure of 11 pounds per square foot. Class B loading gives greater stress than Class A loading for all sizes of wire in use. The difference is greatest for small sizes.

Several important lines have been designed on the assumption of a maximum loading of ½ inch of ice and wind pressure at 6 pounds per square foot, the temperature corresponding to this loading being taken as 0° F. In these same lines the clearance under unequal loadings was calculated on the assumption of five

spans between anchor towers, with no ice on the third span of the lower conductor, and no ice on the first, second, fourth and fifth spans of the upper conductor, but with a loading of ¼ inch of ice on all other spans the temperature being taken as 32° F. and no wind assumed.

VERTICAL AND TRANSVERSE FORCES ON A SUSPENDED WIRE. — The resultant force acting on one foot of a suspended wire is in general made up of three components, viz.:

c = weight of the conductor (including insulation, if any) per foot length, in pounds;
i = weight of the ice coating per foot length of the conductor, in pounds;
h = wind pressure per foot length of the conductor, in pounds.

The weight of the conductor per foot length may be taken directly from the tables in the articles on *Wires and Cables, Bare,* as can also the diameter of the conductor (over the insulation, if any). Let d be this diameter in inches and let t be the thickness of the ice coating, then the weight of the ice coating per foot length of the conductor is

$$i = 1.24\, t\,(d + t). \tag{2}$$

Let p be the wind pressure per square foot of projected area, assumed or calculated from equation (1); then the wind pressure per foot length of the conductor, i.e., the horizontal component of the resultant force, is

$$h = \frac{p\ (d + 2t)}{12}. \tag{3}$$

The vertical component of the resultant force per foot length of conductor, which is equal to the resultant force for no wind, is

$$v = c + i. \tag{4}$$

Values of v and h for various ice thicknesses and various sizes of wires are given in Table II. The values of h are given in the table for a wind pressure of 10 pounds per square foot; these values of h are designated h_0; for any other wind pressure of say p pounds multiply these values by $\frac{p}{10}$. Knowing v and h the resultant force w for any combination of wind and ice loads is readily determined by the formula

$$w = \sqrt{v^2 + h^2}. \tag{5}$$

TABLE II. VERTICAL AND HORIZONTAL LOADING FORCES*

Pounds per Foot of Conductor

The horizontal component h_0 is given for a wind pressure of 10 lb. per sq. ft.; for any other wind pressure of p lb. per sq. ft., $h = \frac{ph_0}{10}$.

The resultant force for any ice thickness and wind pressure is $w = \sqrt{v^2 + h^2}$

CALCULATION OF SAG AND TENSION. — A wire or cable suspended between towers takes the form of a catenary curve. In transmission-line practice the maximum deflection or sag is always small compared to the span, that is, the curve is very flat. The shape of such a flat catenary curve does not differ appreciably from a parabola and, as the approximate parabolic formulas are much simpler than the more exact catenary formulas, they are used instead. The flatness of the curve allows of some further simplifications even in the parabolic formulas, viz., (1) the tension is considered uniform throughout the span, the slight excess of tension at the ends over that at middle being neglected; (2) the change of length of the wire due to elastic stretch or temperature expansion is taken as equal to the change of length of a wire equal in length to the horizontal distance between the points of support.

Notation Used in Sag-tension Formulas. — The following notation, listed alphabetically, will be used throughout the discussion of sag and tension:

A = cross section of the conductor (actual metal cross section) in circular inches = square of diameter in inches; 1 circular inch = 1,000,000 circular mils.

a = coefficient of linear expansion of the conductor per °F.; see Table I above.

D = deflection, in feet, of the lowest point of the conductor when suspended from two points of support at the same elevation and at a distance L apart. (D is measured in the direction of the resultant transverse force.)

e = difference in elevation of the two points of support, in feet.

F = longitudinal *horizontal* component of the stress in the conductor, in pounds. (The resultant stress in the wire at the insulator is equal to $\sqrt{F^2 + H^2 + V^2}$, where V is the weight of the conductor and ice from the insulator to the lowest point of the span, and H is the total wind pressure on half the length of span; H and V in this expression are usually negligible compared with F.)

h = wind pressure in pounds per foot length of conductor assumed perpendicular to the vertical plane through the two points of support; see equation (3) and Table II above.

L = length of span in feet, i.e., the horizontal distance between the two points of support in feet.

l = length in feet of the arc of the curve in which the conductor hangs, i.e., the length of stretched conductor between the two points of support.

M = modulus of elasticity of the conductor in pound-inch units; see Table I above.

$S = \dfrac{vD}{w}$ = sag of the lowest point of the conductor below the horizontal line through the lower point of support; for no wind $S = D$.

T_0 = maximum allowable tension in the conductor in pounds per square inch of its cross section; T_0 is usually taken as one-half the ultimate strength of the conductor; see Table I.

v = vertical force in pounds on a one-foot length of the conductor, including the weight of conductor and the weight of the ice, if any, on it; see equation (4) and Table II above.

$w = \sqrt{v^2 + h^2}$ = resultant load in pounds on a one-foot length of the conductor.

$Z = \dfrac{hD}{w}$ = side swing, in feet, of the middle point of the conductor, measured perpendicularly to the vertical plane through the two points of support.

The various symbols with the subscript "o" will be used to designate the values of the various quantities under the conditions of maximum assumed loading; see paragraph above on *Maximum Loading*.

Fundamental Equations of a Wire Span. — As noted above, a perfectly flexible wire suspended between two points of support hangs in a catenary. The assumption that the wire hangs in a parabola instead of in a catenary is sufficiently accurate for all practical calculations of wire spans, the error in the sag calculated on this assumption being less than 2 per cent of its true value when this sag is less than 0.06 times the length of the span (e.g., less than 60 feet in a 1000-foot span), and the error in the length of the wire calculated on this assumption being less than 0.002 per cent of its true value for the same limiting conditions. The formulas given below are all based on the assumption of a parabola.

Deflection, Sag and Side Swing. — For a given length of span L, loading w, and stress F, the deflection D for the points of support at the same elevation is given by the relation

$$D = \frac{wL^2}{8F}. \tag{6}$$

When there is no wind this is also equal to the vertical sag, that is $S = D$. When there is wind, w is greater than the vertical loading v, and the vertical sag for the points of support at the same elevation is

$$S = \frac{vD}{w} = \frac{vL^2}{8F}. \tag{7}$$

D in equation (7) has the value given by equation (6). When one point of support is at an elevation e above the other, then the vertical sag of the lowest point of the conductor below the lower point of support is

$$S' = S\left(1 - \frac{e}{4S}\right)^2, \tag{8}$$

where S is given by equation (7). The horizontal distance of the lowest point of the conductor from the lower point of support is

$$L' = \frac{L}{2}\left(1 - \frac{e}{4S}\right). \tag{9}$$

The side swing Z of the middle point of the conductor, which is the point which is deflected the maximum distance from the vertical plane through the two points of support, is

$$Z = \frac{hD}{w} = \frac{hL^2}{8F}. \tag{10}$$

D in equation (10) has the value given by equation (6).

Length of Stretched Conductor. — The length of conductor between the two points of support for a given length of span L, loading w, stress F and difference of elevation e, is

$$l = L + \frac{8}{3}\frac{D^2}{L} + \frac{e^2}{2L}, \tag{11}$$

where D has the value given by equation (6), that is, D is the deflection for the same length of span, loading and tension, but for the points of support at the same elevation.

Effect of Changes in Loading and Temperature. — When the loading or the temperature changes, the stress in the conductor will change to some new value, F_0 say, and the deflection will change to some new value, say D_0. Let the new loading be w_0 and the new temperature be t_0, the initial temperature being t; also let a be the coefficient of linear expansion, M the modulus of elasticity, and A the cross section of the conductor in millions of circular mils. Then, when the points of support remain fixed, the following relation must hold

$$\frac{8}{3L^2}(D^2 - D_0^2) = a(t - t_0) + \frac{1.273}{MA}(F - F_0). \qquad (12)$$

The D's in this equation are the same as given by equation (6) for a loading of w and w_0 respectively and stresses of F and F_0 respectively. Note that equation (12) is independent of the difference in elevation of the two points of support; also that the two sets of symbols, with and without the subscripts, refer to *any* two sets of conditions.

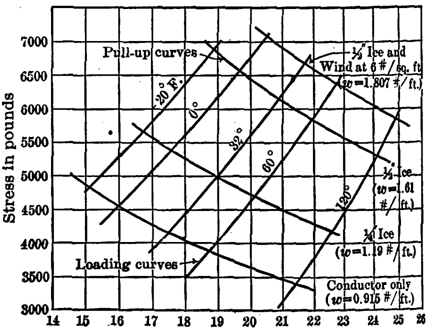

Fig. 8. Stress-Deflection Chart for a 300,000-Circular-Mil, 19-Strand Copper Conductor on an 800-ft. Span

Stress - Deflection Charts (Fig. 8). — In order to apply the above equations to the calculation of clearances under various conditions equation (6), namely

$$D = \frac{wL^2}{8F}, \qquad (13)$$

and equation (12), which may be written

$$F = F_0 - \frac{2.10\,MA}{L^2}D_0^2 - \frac{MAa}{1.273}(t - t_0) + \frac{2.10\,MA}{L^2}D^2, \qquad (14)$$

may be plotted for any given length of span as shown in Fig. 8, with deflection D as abscissas and the stress F as ordinates.

Pull-up Curves. — The curves representing the relation between D and F in equation (13) are equilateral hyperbolas, as many of these curves being drawn as there are loadings to be considered. These hyperbolas may be called "pull-up" curves, since they give the stress to which the wire must be pulled up for any given deflection. In Fig. 8 four pull-up curves are shown, one for the conductor only ($w = 0.915$), conductor coated with ¼ inch of ice but no wind ($w = 1.19$), conductor coated with ½ inch of ice but no wind ($w = 1.61$), and conductor coated with ½ inch of ice and a wind pressure of 6 pounds per foot of projected area of wire ($w = 1.807$), this last being taken as the maximum loading.

Loading Curves. — The curves representing the relation between D and F in equation (14) are parabolas with vertical axes, as many of these curves being drawn as there are temperatures to be considered. These parabolas may be called "loading curves," since for a change in loading (at constant temperature) they give the relation which must exist between the new stress and new deflection produced. In order to plot these curves it is necessary to assume a maximum allowable tension, say T_0 pounds per square inch, a maximum load-

ing w_0, and the minimum temperature t_0 at which this loading is assumed to occur. Then

$$F_0 = \frac{AT_0}{1.273} \quad \text{and} \quad D_0 = \frac{w_0 L^2}{8 F_0},$$

and for any given temperature t all the terms in the right-hand member of (14) are constants except the last term, which varies as D^2. In Fig. 8 the maximum allowable tension T_0 is taken as 30,000 pounds per square inch, the maximum loading w_0 as 1.807 pounds per foot length, and the minimum temperature under maximum loading as 0° F. Then $F_0 = 7065$ pounds and $D_0 = 20.5$, which fixes one point on the 0° loading curve, and the other points on this curve are calculated directly from (14) by putting $t = 0$. For any other temperature, equation (14) gives the same shaped parabola as for 0°, but each point of the curve is shifted vertically downward a distance $\frac{MAa}{1.273}$ for each degree increase of temperature. Hence it is only necessary to calculate the 0° loading curve, and the loading curve for any other temperature can be readily plotted by the use of a pair of dividers.

Stringing Stresses and Deflections. — In stringing cable it is essential that the stress or deflection be correct for the stringing temperature, otherwise the maximum stress will be more than safe or the clearance to ground less than safe due to maximum deflection exceeding the designed amount. To insure proper stringing, curves of temperature-sag and temperature-stress are plotted from the stress-deflection curves. These curves are for no wind and no ice. Fig. 9 shows such curves for the 800-foot span plotted from Fig. 8. For example, if the cable is strung at 70° F., then it should be given a deflection (vertical sag) of 19.25 feet, provided the points of support are at the same elevation, or at a stress of 3800 pounds, this stress being independent of the difference of elevation of the two points of support. If there is a difference of elevation of 30 feet, say, between the two points of support, then from equation (8a), the cable should be drawn up until the sag of the lowest point below the lower point of support is

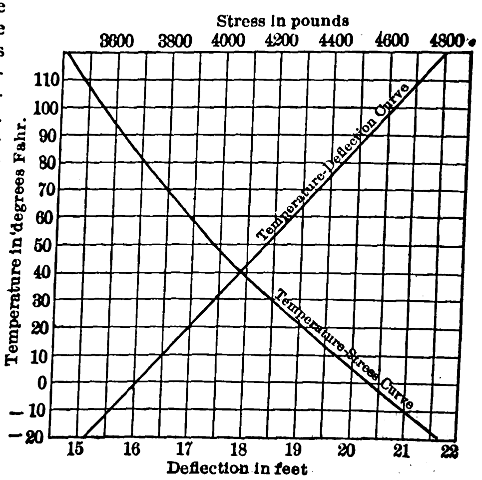

Fig. 9. Stringing Chart

$$S' = 19.25\left(1 - \frac{30}{4 \times 19.25}\right)^2 = 7.17 \text{ feet},$$

and the stress will then be 3800 pounds.

Stress and Deflection in Spans of Unequal Length. — By stringing cables according to the stress determined for each particular length of span, the maxi-

mum allowable tension will be reached in all spans under maximum loading conditions. Under other loading conditions the tension will be unequal where span lengths are not the same. This is shown in Fig. 10 which is plotted for the same conditions as stated in the title of Fig. 8, but for spans of from 600 to 900 feet in length. Fig. 11 shows the corresponding deflections.

The unequal stresses on the two sides of the insulator will tend to bend the tower or insulator pin, but any motion of the point of support will tend to equalize the stresses. When suspension insulators are used, the stresses are practically equalized, since the insulator is free to move. It should be noted that the motion of the insulator necessary to equalize the stresses is small. When suspension insulators are used the cable is therefore strung at a tension corresponding to the average length of span. When the cable is thus strung the tension under minimum temperature and maximum loading will usually exceed the assumed tension in the shorter spans and be less than the assumed tension in the longer spans. Similarly, under maximum temperature conditions, the longer spans will have a sag in excess of the value calculated on the assumption of the maximum allowable tension being reached with maximum loading, and the shorter spans will have a sag less than the calculated value. The actual stresses and deflections can be calculated by the method given in the following section.

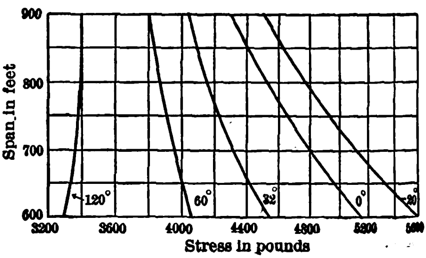

Fig. 10.

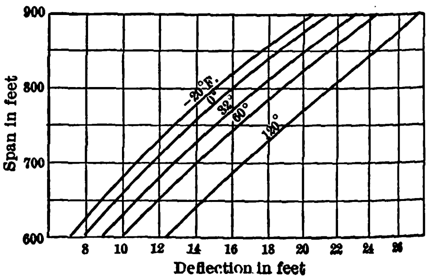

Fig. 11.

Calculation of Stresses in Unequally Loaded Spans.* — When suspension insulators are used, any tendency of the stresses in two adjacent spans to become unequal will produce such a deflection of the insulator, in the direction of the span with greater stress, as will establish equilibrium in the line. This state of affairs will occur (1) when adjacent spans carry unequal ice loads, (2) when the wire on one side of the insulator breaks, and (3) to a slight extent with changes in temperature when the adjacent spans are unequal in length, as noted above. The following method of calculating the "equilibrium" stresses in the wires and corresponding sags is applicable to all cases of initially unbalanced stresses, irrespective of their cause. The method may also be used to calculate the stress and sag in spans supported on pin insulators, provided the moment of bending of the pin and of the pole or tower is known or can be calculated.

* From lecture notes by Dr. H. Pender.

Change of Stress Due to Change in Length of Span. — When the length L of the span (i.e., distance between points of support) increases by λ inches, due to a horizontal displacement of the insulators (without slipping of the wire), the stress in the wire is increased by the same amount as would be produced by a fall in temperature of

$$t - t' = \frac{\lambda}{12\, aL} \qquad \text{or} \qquad t' = t - \frac{\lambda}{12\, aL}, \tag{15}$$

degrees Fahrenheit, where t is the actual temperature and t' may be called the "equivalent" temperature corresponding to the change in length λ. In this equation λ is the actual increase in the distance between the points of support in inches, a the temperature coefficient of linear expansion per °F., and L the original length of the span in feet. For example, in an 800-foot span of copper wire an increase of 1 inch in L corresponds to a drop of temperature of $1 \div (12 \times 9.6 \times 10^{-6} \times 800) = 10.85$ degrees, and an increase in length of λ inches corresponds to a drop of temperature of $t - t' = 10.85\,\lambda$ degrees.

Hence the stress-deflection chart for any given length of span, see Fig. 8, may be used directly to determine the stress in the wire after any change in the length of the span, due to the deflection of the insulator. For example, consider an 800-foot span of 300,000-circular-mil, bare, copper conductor, at 32° F., without ice or wind, initially stressed to 4170 pounds, and let the length of the span be increased 4 inches as the result of the deflection of the insulators by this amount. This increase in length of span will then give the same stress in the wire as would be produced if the temperature fell from 32° to $t' = 32 - 4 \times 10.85 = -11.4°$. The point at which the loading curve (Fig. 8) corresponding to a temperature of $-11.4°$ crosses the pull-up curve for conductor only gives the new stress, viz., 4700 pounds.

Horizontal Pull of Insulator. — Referring to Fig. 12, let m = the horizontal distance in inches (measured along the span) which any insulator is deflected from the vertical, taken positive when to the right, say, and negative when to the left. Let x = the length of the insulator string in inches, i.e., distance from point of attachment to tower to point of attachment to wire; V = total weight of wire and ice between the lowest point of the wire in the span to the left of the insulator and the lowest point of the wire in the span to the right of the insulator plus one-half the weight of the insulator; H = total wind pressure on the length of wire between the middle points of the two adjacent spans, plus half the wind pressure on the insulator; and put $W = \sqrt{V^2 + H^2}$. Then the horizontal component of the pull of the insulator toward the left along the line of the span is *

$$P = \frac{m}{\sqrt{x^2 - m^2}} \cdot W. \tag{16}$$

For example, consider two adjacent spans of 300,000-circular-mil copper, each 800 feet long and with points of support at the same elevation. Let the span to the left be free of ice and let the one to the right have a ¼-inch ice coating; assume the insulator to be 60 inches long and to weigh 100 pounds. Then for no wind $H = 0$, $V = 1.19 \times 400 + 0.915 \times 400 + 100/2 = 892$ pounds. Whence for deflections of the insulator of less than 12 inches the horizontal pull of the insulator is $P = (892 \times m) \div 60 = 14.9\, m$, or 14.9 pounds per inch deflection.

* When m is less than 20 per cent of x this may be written, with an error of less than 2 per cent,

$$P = \frac{m}{x} W. \tag{16a}$$

Stresses in a Series of Spans When Points of Support are not Fixed. — Referring to Fig. 12, let the left-hand end of span No. 1 be anchored, and assume the insulator at the right-hand end to be deflected a horizontal distance of m_1 inches, due, for example, to a change in the loading on the succeeding

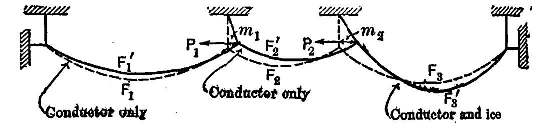

Fig. 12.

spans (or to a change in temperature when the spans are of unequal length). From equation (15) calculate the "equivalent" temperature t_1' corresponding to this change in length, and from the pull-up curve in Fig. 8 corresponding to the assumed loading w_1 of this span find the stress on this curve corresponding to a temperature of t_1' degrees; call this stress F_1'.

Next calculate the transverse and vertical loads on the insulator, viz., H_1 and V_1, and the resultant load $W_1 = \sqrt{V_1^2 + H_1^2}$, as explained in the preceding section. Then from equation (16) or (16a) calculate the horizontal pull P_1 of the insulator. The stress in the second span, assuming the value of m_1 chosen at the start is correct, must then be

$$F_2' = F_1' + P_1. \tag{17}$$

t_2' is then determined from F_2' on the pull-up curve. From equation (15) the corresponding increase in the length of span No. 2 must then be

$$\lambda_2 = 12\, aL_2\,(t - t_2'), \tag{18}$$

where L_2 is the length of the second span. The corresponding deflection of the insulator at the right-hand end of span No. 2 must then be

$$m_2 = m_1 + \lambda_2, \tag{19}$$

always taking the insulator deflection positive when to the right, say.

Using the values of λ_2 and m_2 thus found, calculate the λ_3 and m_3 in exactly the same manner as λ_2 and m_2 were calculated, and similarly for the succeeding spans until the next anchor tower is reached. For the anchor tower at the right-hand end of the n-th span, say, the deflection of the insulator must be zero, viz.,

$$m_n = 0. \tag{20}$$

If m_n as calculated comes out greater than zero, then the assumed value of m_1 is too great; if m_n comes out less than zero the assumed value of m_1 is too small. By calculating m_n for two or three assumed values of m_1, and plotting m_n as ordinates against m_1 as abscissas, the correct value of m_1 will be where this curve crosses the axis of abscissas. Using this correct value of m_1, the stresses and deflections in each span may then be accurately calculated by the process just given, using the Stress-Deflection Chart, Fig. 8. The complete process is best shown by an example.

Example. — Consider the case of three spans between anchor towers (Fig. 12) all of the same length, 800 feet, and all supports at the same elevation, 300,000-circular-mil copper being used for the conductor. Let the temperature be 32° F., and let the middle span have a ¼-inch ice coating but the other two spans have no ice on them; also assume no wind. The Stress-Deflection Chart given in Fig. 8 then applies directly, provided the wires are strung in accordance therewith. Assume that each insulator weighs 100 pounds and has a length of

60 inches. Then for an increase of λ inches in the length of any span, the "equivalent" temperature is, from equation (15),

$$t' = 32 - 10.85\lambda$$

or if the equivalent temperature rise t' is known

$$\lambda = 0.092\,(32 - t').$$

The horizontal pull of any insulator for a deflection of m inches (small compared with the length of the insulator) is, from equation (16a),

$$P = 14.9\,m.$$

In the following table are given the calculations for assumed values of m_1 of 1, 2, 3 and 4 inches, and in Fig. 13 are plotted the corresponding calculated values of m_3 against m_1. It is seen that the relation between m_3 and m_1 is practically a straight line cutting the horizontal axis at $m_1 = 2.4$, which is therefore the correct value of m_1. The calculations for $m_1 = 2.4$ inches are given in the last column of the table. Hence the stresses and deflections in the two end spans (without ice) are $F_1' = F_3' = 4460$ pounds and $D_1' = D_3' = 16.3$ feet respectively, and the stress and deflection in the middle span loaded with ¼-inch of ice are $F_2' = 4496$ pounds and $D_2' = 21.1$ feet respectively, the deflections being read directly from Fig. 8 corresponding to the proper stresses and loadings (w).

LOCATION OF TOWERS AND DETERMINATION OF CLEARANCES.—The height of towers is determined so as to give some specified minimum clearance from conductor to ground for some length of span chosen as a nominal standard on the basis of level ground. In practice the ground is rarely level and the towers are actually located to conform to the irregularities of the ground. In locating towers of a given height the spans are made as long as possible consistent with maintaining the ground clearance. The irregularities of the ground are ordinarily advantageous and permit of slightly longer spans on the average than could be obtained with the same height of towers on level ground.

Profile and Plan of Right-of-Way. — In order to locate towers properly it is necessary to have a profile of the right-of-way. Profiles are conveniently plotted on standard ruled profile section paper to a vertical scale of 20 feet to the inch and a horizontal scale of 200 feet to the inch. Three profiles are desirable, one along the center of the tower line and one on each side, say at each edge of right-of-way, as shown on Fig. 14 at *A*, *B* and *C*. The two side profiles indicate the amount and direction of the slope of the ground across the line, which must be allowed for in determining ground clearance and foundation or tower extensions.

A plan of the right-of-way is of course also necessary for determining the construction at angles in the line, and the clearances from the conductor to the edge of the right-of-way when the conductor is deflected horizontally by the wind. Such a plan is shown at the bottom of Fig. 14.

Templates for Locating Towers. — Three templates are required, one for ground clearance with maximum sag, marked *M* in Fig. 14, one for uplift at times of minimum sag, marked *N*, and one for maximum side swing, marked *Z*. These are cut from thin celluloid and are to the same horizontal and vertical scales as used for the profile and plan of the right-of-way.

Since the curvature of the catenary or parabola in which the wire hangs depends only on the tension and loading and not on the length of the span or on the difference in elevation of the points of support, all spans having the same tension and loading can be drawn (for any one predetermined scale) from a single template, irrespective of their lengths or of the differences in elevation of the points of support. However, when the elevations of the points of support are not the same, the lowest point of the curve is shifted from the middle of the span toward the lower support, but the axis of the curve remains vertical.

Construction of Maximum Sag Template *M*. — The maximum sag is found from the Stress-Deflection Chart, Fig. 8, and may be the deflection corresponding to the maximum temperature, and conductor only, e.g., 21.4 feet in Fig. 8, or may be the deflection corresponding to 32° F. and the maximum ice loading. Wind will increase this deflection but will not increase the *vertical sag*. Call S_m this maximum sag. Then the equation of the maximum sag template, or template *M*, is

$$y = \left(\frac{4\,S_m}{L^2}\right) x^2, \tag{21}$$

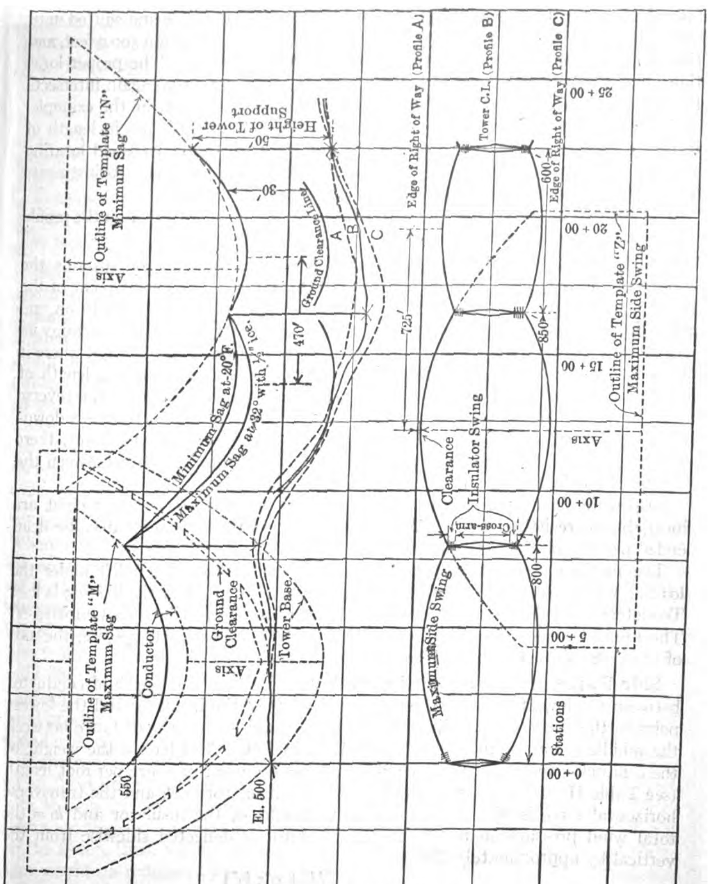
where L is the length of the particular span for which the maximum sag is S_m, and the origin of the curve is its lowest point and the axis of y is vertical; all dimensions are in feet. Three parabolic curves are given by this template; the top curve represents the position of the cable and is drawn on the basis of the average span under the maximum load; the middle curve is a similar parabola below the upper curve a distance equal to the minimum allowable clearance to ground; the bottom curve is another similar parabola below the upper curve by a distance equal to the height of cable above ground at the support.

Construction of Minimum Sag Template *N*. — The minimum sag is also found from the Stress-Deflection Chart, and is usually the deflection corresponding to the minimum temperature and conductor only, e.g., 15.1 feet in Fig. 8. Call this sag S_n; then the equation of the minimum sag template, or template *N*, is

$$y = \left(\frac{4\,S_n}{L^2}\right) x^2. \tag{22}$$

Construction of Maximum Side-swing Template *Z*. — The maximum side swing occurs at time of maximum wind pressure and may be at

Fig. 14. Chart Showing Use of Templates in Locating Towers and Determining Clearances



maximum temperature or may be at 32° F. when covered with ice. In the latter case the side swing depends on the shape (circular or elliptical) of the ice covering and its specific gravity. For a circular covering of solid ice one particular thickness (usually but not necessarily the maximum thickness) gives the greatest side swing. For example, in Fig. 8, the maximum side swing occurs at $D = 21.7$ and $w = 1.807$, and its value is, see equation (10), $Z = (0.815 \times 21.7) \div 1.807 = 9.8$ feet, 0.815 being the wind pressure per foot of wire. Calling the maximum side swing Z_m, then the equation of the side swing template, or template Z, is

$$y = \left(\frac{4 Z_m}{L^2}\right) x^2. \tag{23}$$

Locating Towers by Means of Template *M*.—Choose a starting point, as shown for example in Fig. 14, at station 0 + 00, elevation 500.0 feet for the first tower location. The template *M* is then placed over the profile and shifted until its axis is vertical and the lower curve is at station 0 + 00, elevation 500.0 feet, and the middle curve is tangent to the ground profile as shown. The proper location for the second tower is at the point where the lower curve again intersects the ground profile, or at station 8 + 00, elevation 506.0 feet, in the example. The operation is then repeated for the next tower. Adjustments in length of span are usually necessary to meet local conditions, in order to avoid locating towers in roads or swamps and to bring towers at angle points. Adjustments which increase the ground clearance are of course allowable.

The position of the conductors with maximum sag may be drawn on the profile from the top curve of the template.

Uplift on Insulator; Use of Template *N*.—An insulator sustains the weight of the lengths of conductor from the insulator to the lowest point of the span on each side. If the conductor leaves the insulator horizontally on one side, the lowest point of that span is at the insulator, which then sustains no weight due to that span. If the conductor has an upward inclination where it leaves an insulator, it is exerting an uplift equal to the weight of a length of conductor extending from the insulator along the span produced in the reverse direction to the lowest point of the parabola. Where the conductor has a downward inclination on one side and upward on the other side of the insulator, there will be a weight or uplift on the insulator equal to the difference between the weight of conductor on one side and uplift on the other.

Suspension insulators when used hanging downward to sustain weight are incapable of resisting uplift. Where uplift occurs the conductor may be dead ended or may be tied down or weighted down.

The method used for locating towers ordinarily precludes uplift under the loading which gives maximum sag, but uplift may occur when the loading is less. To determine this the minimum sag is drawn on the profile with template *N*. The minimum sag curve is drawn between points of support, keeping the axis of the parabola vertical as before.

Side Swing of Suspension Insulators.—Let l_1 = the length of conductor between the lowest point in the span to the left of the insulator and the lowest point in the span to the right of the insulator, and let l_2 = the distance between the middle points of these two spans, both in feet. Also let v = the weight of the conductor and ice per foot length, and h = the wind pressure per foot length (see Table II). Then the vertical pull on the insulator is vl_1 and the transverse horizontal force is hl_2. Also let v_1 = the weight of the insulator and h_1 = the total wind pressure on it. Then the insulator is deflected sidewise from the vertical by approximately the angle

$$\theta = \tan^{-1}\left[\frac{hl_2 + 0.5\, h_1}{vl_1 + 0.5\, v_1}\right]. \tag{24}$$

Usually the weight of the insulator and the wind pressure on it are negligible compared with the weight and wind pressure on the conductor, in which case

$$\theta = \tan^{-1}\left(\frac{hl_2}{vl_1}\right). \qquad (24a)$$

When the points of support are at the same elevation $l_1 = l_2$ and

$$\theta = \tan^{-1}\frac{h}{v}. \qquad (24b)$$

Calling X the length of the insulator in feet then the transverse horizontal deflection of the insulator is $X \sin \theta$ feet.

For example, consider the side swing of the third insulator (from the left) in Fig. 14. Then $l_1 = 470$, $l_2 = 850/2 + 600/2 = 725$, $v = 1.61$ (for 300,000-circular-mil conductor with ½ inch of ice), and $h = 0.82$ (for wind pressure of 6 pounds per square foot). Whence, neglecting the weight of the insulator and the wind pressure on it,

$$\theta = \tan^{-1}\frac{0.82 \times 725}{1.61 \times 470} = 38°.$$

If the insulator is 5 feet long, the transverse horizontal deflection is then $5 \sin 38° = 3.1$ feet.

If the angle of swing as thus determined is excessive the cables and insulators will be lifted up into the cross arms at times of low temperatures and high winds. The remedy is the same as in case of direct uplift.

Side Clearance; Use of Template *Z*. — Where a right-of-way of definite width is obtained it is necessary to determine whether the conductor will swing beyond the edge of the right-of-way. Therefore after the towers have been located by the use of the profile they should be marked on the plan and the side swing marked in from template *Z*, as shown in Fig. 14. In determining side swing, the swing of the insulator (if suspension type) must be allowed for, as well as the side swing of the conductor. Adequate margin should be allowed between the extreme position of conductor and the edge of the right-of-way, so that a safe clearance will be preserved from any structures erected adjacent thereto. Where extraordinarily long spans must be used, an adequate extra width of right-of-way should be obtained in the first place.

Loss of Clearance Between Conductors Due to Unequal Ice Loading.— Where one span is loaded with ice and the one immediately below it is not, the clearance is reduced. This condition may sometimes arise due to the ice falling off the lower wire before it falls off the upper wire. Where the wires are directly over each other the normal clearance must be great enough to prevent the crossing of wires under these conditions. For ice loading without wind, clearance under unequal loading is most easily obtained by offsetting the wires horizontally for the required clearance instead of increasing the vertical clearance. However, to prevent crossing of the unequally loaded wires when deflected by wind pressure, this horizontal offset must be considerable, as the clearance must then be obtained between the wires in their inclined positions.

If the conductors to which Fig. 8 refer are normally 10 feet apart vertically on an 800-foot span, the sag would be 17.5 feet without ice at 32° F., 19.0 feet with ¼-inch ice, and 20.9 feet with ½-inch ice at 32° F. Consequently, if two cables are used one above the other, and ice should form on the upper but not on the lower, then, assuming fixed points of support (pin insulators), the clearance would be reduced by 3.4 feet for ½-inch ice, and 1.5 feet for ¼-inch ice, making the clearances 6.6 feet and 8.5 feet respectively, instead of 10 feet.

Where suspension insulators are used the reduction of clearance from unequal ice loading is greater. If one span is loaded with ice and the adjacent spans of the same wire are not loaded, the sag of the loaded span will be increased because the insulators will swing toward that span. Similarly if one span is unloaded and adjacent spans are loaded, the sag will be decreased. The minimum clearance occurs where only one span of the upper wire is loaded and is immediately over the only unloaded span of the lower wire. The actual reduction is readily calculated by the method given above in the section on *Calculation of Stresses in Unequally Loaded Spans*, p. 1696. The amount of reduction depends on the number of spans between anchor towers, and the distance from the anchor towers at which the unbalanced loading occurs. For a 300,000-circular-mil copper cable on 800-foot spans at 32° F. with unequal loadings on sections of one, two, three and five spans (see Fig. 15) the assumed conditions of unequal loading and the loss of clearance are as follows:

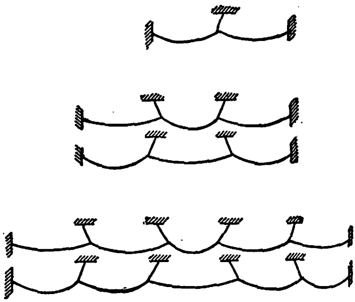


Fig. 15.

Number of spans between anchor towers	1	2	3	5
Upper conductor; ¼-inch ice on spans Nos.:*	1	1	2	3
Lower conductor; ¼-inch ice on spans Nos.:*	...	2	1, 3	1, 2, 4, 5
Sag of middle span of upper conductor, feet	19.0	20.5	21.1	21.6
Sag of middle span of lower conductor, feet	17.5	15.9	15.5	15.2
Loss of clearance in middle span, feet	1.5	4.6	5.6	6.4

* The other spans assumed to have no ice load.

Stresses and Deflections Due to Broken Conductors.—When a conductor breaks in a span supported by suspension insulators, the insulators adjacent to the broken span swing up into line with the cable, throwing increased slack into the unbroken part of the cable equal to the length of the insulator. This slack divides between the unbroken spans, increasing the deflection of each. The stresses and deflections of the unbroken spans may be determined by the method given above in the section on *Calculation of Stresses in Unequally Loaded Spans*, p. 1696, calling the span in which the break occurs span No. 1.

ERECTION OF TRANSMISSION LINES.—The preliminary work in constructing a transmission line includes the clearing of the right-of-way, moving of buildings (if necessary), building roads, bridges, fences, gates, etc., to make the right-of-way passable. If the telephone line is to be supported on separate structures, this is generally built in advance of the main line and used during the rest of the construction.

After the towers are in place and the insulators placed, the wires and cables are strung. The reels are distributed and spaced according to the length of cable on each. The reels of heavy cable are supported on reel jacks. The lighter wire and cable is usually drawn out on the ground and carried or hauled up on the supporting structures. Heavy cables are drawn over rollers or sheaves attached to the towers at approximately the final point of support. The pulling

out of wires and cables is usually done with horses, but under favorable conditions a traction engine or hoisting engine can be used. Where lines parallel railroads they have been pulled out successfully with locomotives. Care should be taken in drawing out the cable so as not to scratch or injure it by sharp bends or faulty cable grips, or by dragging it over sharp stones. See also the article on *Wires and Cables, Bare.*

After the cable is drawn out and is in place on the sheaves on the towers, it should be adjusted to the proper sag by using dynamometers for measuring the tension. In order to have uniform tension in all spans when pulling several at one time, the cable should be free to move at all points of support. Wires and cables should be clamped or tied in place while under the proper tension corresponding to the temperature at time of stringing. Wind loads on cables or wires are generally not of an amount during wire stringing to require allowance for additional tension. Splicing sleeves are twisted by hand wrenches in the smaller sizes and by splicing machines for the larger sizes.

At anchor towers loose jumpers must be bent to shape and not left so that they may ground on the tower due to twist of cable, pressure of wind or weight of sleet.

Where ground wires or telephone wires are also on the tower, it is equally important that they be strung at the proper tension; otherwise they may cross and ground the conductors.

Suspension towers (i.e., those intermediate between the dead-end towers) are ordinarily not strong enough to stand the strain of dead-ended cables during high winds and heavy sleet storms; consequently care must be used if cables are temporarily dead ended on them during construction.

Transposition of Transmission Lines. — (*See also Telephone Lines.*) Transpositions are not necessary for the proper operation of an isolated transmission line, but are used to diminish the inductive effects of the transmission line on neighboring circuits. The number of transpositions required depends principally on the sensitiveness and proximity of other circuits, especially telephone lines and on the distance that such lines parallel the transmission line, and also to a lesser degree on the current and voltage of the transmission line.

Where the voltage of transmission is 2200 or less the length of exposure (i.e., distance between two successive transposition points) is usually insufficient to require transpositions and, when the voltage is over 60,000, the lines are often at sufficient distance from nearest telephone line to make transpositions unnecessary. For voltages above 2200 and not over 60,000 a telephone line is ordinarily run the whole distance on the same poles or towers with a transmission line, thereby making transpositions necessary. Transpositions on such transmission lines are ordinarily located three miles or more apart, the telephone line also being transposed every 500 or 600 feet.

Each transposition of a three-phase line ordinarily consists of a spiral of one-third of a turn. Three transpositions give a complete spiral and bring the phases back to their original position. A line is ordinarily transposed by giving it one or more complete spirals, the transpositions being located so as to divide the line into approximately equal sections. For one complete spiral two transpositions dividing the line into thirds are sufficient, though the equivalent of a third transposition is necessary at one end if the phases are to have the same relative position in the station wiring at each end.

Special poles or towers are usually necessary at transposition points.

TESTS AND INSPECTION OF TRANSMISSION LINES. — Tests on transmission lines include testing of the several parts; conductors, insulators, pins, clamps, ties, towers, etc., and are described in the articles on ***Wires and***

Cables; Insulators for Overhead Lines; Poles for Overhead Lines, Cross Arms; Towers. The efficiency and other electrical characteristics of transmission lines can be computed with such certainty that tests are not necessary to determine these features, though the calculations are occasionally checked by observations made during actual operation.

When a line is completed it should be carefully inspected to see that all joints have been made, all insulators put on, etc. Moreover, before starting continuous operation, it is advisable to apply voltage in order to make sure that the line is not open circuited, short-circuited or grounded.

Where two or more transmission lines are to be in parallel, or where a new line connects two points already connected by other lines, it is necessary to test out to find corresponding phases before connecting in multiple, especially if any of the lines have transpositions.

OPERATION. — Patrolmen are usually located between ten and twenty miles apart, depending on the character of the country. The coöperation of people living along the line must be obtained in order to prevent damage by breaking of insulators, throwing wires over the conductors, blasting rocks or stumps near the line, etc. Patrolmen should inspect the line regularly and keep weeds, brush and inflammable material away from the poles and towers. They should note the condition of the foundations, towers, poles, insulators and conductors. In addition they should make minor and emergency repairs on the line.

Section switches are often installed at each patrolman's house. By manipulating these switches any section of line may then be tested for faults.

The proper maintenance of a line includes resetting foundations that have settled; covering of foundations with earth to proper depth after heavy rains; repainting of towers before they are affected by rust; renewal of rusted ground cables; replacement of cracked or partially defective insulators that have not failed; correcting sag of any cable where sag has changed due to stretch of cable, change of length during emergency repairs, etc.

Telephone Connections. — A good telephone line is essential and the patrolmen should report by telephone at regular intervals. As a convenience in operation, telephones are installed or connections are provided for a portable telephone set at intervals of three or four miles along the line. For the higher potential lines protection must be provided for the person using telephone. The usual protection includes insulated stools, telephone insulating transformers, drainage coils, telephone lightning arresters and fuses.

COSTS OF TRANSMISSION LINES. — To obtain an accurate estimate of the cost of a transmission line the cost of the various elements should be separately determined. The following over-all costs are given as a rough guide in preliminary estimating.

Cost of Right-of-Way. — The cost of the right-of-way for a low-voltage line ranges from a nominal amount for a line on public roads, to $10,000 per mile or more for a private right-of-way in thickly settled districts. A right-of-way 100 feet wide requires approximately 12 acres per mile, which for farming land at $200 per acre, amounts to $2400 per mile. Land values may be expected to average considerably higher for right-of-way than for farming, especially if a strip of land is desired crossing a farm diagonally.

The right-of-way for high-voltage tower lines should be estimated liberally as such lines should have long spans and few angles, and cannot be diverted around expensive property and obstructions as readily as short-span wooden-pole lines.

Effect of Size and Cost of Conductor on Total Cost. — The size and cost per pound of conductors greatly affect the cost of a line. A circuit of 3

No. 0000 cables costs about $1500 per mile with copper at 14.4 cents per pound and $2000 per mile at 19.2 cents per pound. The cost of smaller cables is proportionally less; No. 0 being about one-half, No. 3 about one-fourth and No. 6 about one-eighth the cost of No. 0000. Thus the copper cost of a three-wire line will range from about $200 per mile for No. 6 at 15.6 cents per pound to $2000 per mile for No. 0000 at 19.2 cents per pound.

For the same power loss in the line aluminum conductors usually cost about 10 per cent less than copper.

Total Structural Cost of Wooden Pole Lines. — The structural cost of a wooden-pole transmission line ordinarily ranges from about $1500 per mile for a 11,000-volt line with 3 No. 6 wires to about $4000 per mile for a 55,000-volt line with 3 No. 0000 wires, excluding the cost of right-of-way. To the structural cost and cost of right-of-way should be added the charges for engineering, contractor's services, superintendence, tools and equipment, etc., which may amount to from 20 to 40 per cent of the structural cost.

Total Structural Cost of Tower Lines. — The cost of light tower lines for 55,000 volts with 3 No. 0000 wires may be as low as for a wooden pole line, i.e., about $4000 per mile. For 110,000 volts with three 300,000-circular-mil wires the cost may be about $8000 per mile or more. The cost of towers proper varies greatly according to the views of the designers as to what risks are proper in design, that is, the severity of assumed wind and ice loadings, and the factors of safety. The cost of foundations is very small when simple steel stubs are used in very firm ground, but foundations add greatly to the cost of a line when concrete or steel structures are used, so designed as to make the strength, rigidity and holding power of the foundations actually equal to the strength of the tower under reasonably unfavorable conditions of ground. See article on *Towers for Transmission Lines*.

[R. A. PHILIP, H. F. THOMSON and E. A. EKERN.]

TRIGONOMETRIC FUNCTIONS. — (*See also Derivatives; Integrals; Series, Mathematical; Trigonometry.*) The trigonometric functions of an angle are the ratios to one another of the various sides of a right triangle having the given angle as one of its angles. Referring to Fig. 1, let B, P and H be the three sides of a triangle. Then the trigonometric functions of the angle x are

sine of x, abbreviated $\sin x = \frac{P}{H}$; cotangent of x, abbreviated $\cot x = \frac{B}{P}$;

cosine of x, abbreviated $\cos x = \frac{B}{H}$; secant of x, abbreviated $\sec x = \frac{H}{B}$;

tangent of x, abbreviated $\tan x = \frac{P}{B}$; cosecant of x, abbreviated $\csc x = \frac{H}{P}$.

When B, P and H are limited to the three sides of a right triangle, the above definitions are directly applicable only to angles lying between 0 and 90°. The definitions, however, may be extended by considering the point A (Fig. 2) as

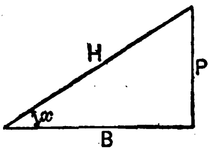

Fig. 1.

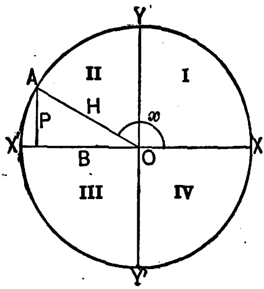

Fig. 2.

describing a circle of radius OA with the center at O. Let XX' be the horizontal diameter and YY' the vertical diameter of this circle, and call P the perpendicular distance from A to the line XX' and B the horizontal distance from A to YY'. P is to be considered positive when A lies above XX', negative when below. B is considered positive when A is to the right of YY' and negative when to the left. The four quarters of the circle are called quadrants, and are designated as the first, second, third and fourth quadrants as indicated. The angle is said to lie in the quadrant in which the point A lies. In Fig. 2 the angle x is in the second quadrant.

ALGEBRAIC SIGNS OF THE FUNCTIONS

	Sine	Cosine	Tangent
Angle in first quadrant....................	+	+	+
Angle in second quadrant..................	+	−	−
Angle in third quadrant....................	−	−	+
Angle in fourth quadrant..................	−	+	−

Period. — From the above definitions it is evident that adding 2π radians or 360° to an angle does not change the value of any of its functions, that is, these functions repeat themselves every time the angle increases by the 2π radians or 360°. They are therefore said to have a period equal to 2π radians or 360°.

Functions of Angles in Any Quadrant in Terms of Angles in First Quadrant.—

$$\sin(-x) = -\sin x, \qquad \sin(90+x) = \cos x,$$
$$\cos(-x) = \cos x, \qquad \cos(90+x) = -\sin x,$$
$$\tan(-x) = -\tan x, \qquad \tan(90+x) = -\cot x,$$

$$\sin(180-x) = \sin x, \qquad \sin(180+x) = -\sin x,$$
$$\cos(180-x) = -\cos x, \qquad \cos(180+x) = -\cos x,$$
$$\tan(180-x) = -\tan x, \qquad \tan(180+x) = \tan x,$$

$$\sin(270-x) = -\cos x, \qquad \sin(270+x) = -\cos x,$$
$$\cos(270-x) = -\sin x, \qquad \cos(270+x) = \sin x,$$
$$\tan(270-x) = \cot x, \qquad \tan(270+x) = -\cot x.$$

Table of Trigonometric Functions. — By making use of the above relations the functions of any angle may be obtained from a table giving the values of the functions for angles between 0 and 90°. Such a table is given below. For the cot, sec and csc take the reciprocals of the tan, cos and sin respectively.

Example of Use of Table. — sin 21.6° = 0.3681, cos 21.6° = 0.9298, tan 21.6° = 0.3959; sin 107° = sin (180° − 107°) = sin 73° = 0.9563, cos 107° = − cos 73° = − 0.2924, tan 107° = − tan 73° = − 3.2709.

Anti-functions. — If $a = \sin x$, then x is the angle whose sine is a; this may be expressed symbolically $x = \sin^{-1} a$, which is read "x equals the angle whose sine is a." The angle x is also called the "anti-sine" or the "inverse sine" of a. Similar notation is used for the other functions; for example, $x = \cos^{-1} b$ is used to express the relation that x is the angle whose cosine is b. At least two "anti-functions" must be known to completely determine the quadrant in which an angle lies; for example, if $x = \sin^{-1} 0.5$ then x may be either $30°$ or $150°$, but if we also have $x = \cos^{-1} 0.866$, then x must equal $30°$, while if $x = \cos^{-1}(-0.866)$, then x must equal $150°$.

Anti-functions may be taken from the table given above by finding the angle in the margin corresponding to the function in the table. *Example:* $\sin^{-1} 0.319 = 18.6°$ or $180° - 18.6° = 161.4°$.

Versine. — The expression $(1 - \cos x)$ is called the "versine" of x.

Relations Among Functions of the Same Angle. —

$$\tan x = \frac{\sin x}{\cos x} = \frac{1}{\cot x}, \qquad \sin^2 x + \cos^2 x = 1,$$

$$\sec x = \frac{1}{\cos x}, \qquad 1 + \tan^2 x = \frac{1}{\cos^2 x},$$

$$\csc x = \frac{1}{\sin x}, \qquad 1 + \cot^2 x = \frac{1}{\sin^2 x},$$

$$\sin(90 - x) = \cos x, \qquad \sin(-x) = -\sin x,$$

$$\cos(90 - x) = \sin x, \qquad \cos(-x) = \cos x,$$

$$\tan(90 - x) = \cot x, \qquad \tan(-x) = -\tan x.$$

Sum and Difference of Two Angles. —

$$\sin(x + y) = \sin x \cos y + \cos x \sin y,$$

$$\cos(x + y) = \cos x \cos y - \sin x \sin y,$$

$$\tan(x + y) = \frac{\tan x + \tan y}{1 - \tan x \tan y},$$

$$\sin(x - y) = \sin x \cos y - \cos x \sin y,$$

$$\cos(x - y) = \cos x \cos y + \sin x \sin y,$$

$$\tan(x - y) = \frac{\tan x - \tan y}{1 + \tan x \tan y}.$$

Product of the Functions of Two Angles. —

$$\sin x \sin y = \tfrac{1}{2}[\cos(x - y) - \cos(x + y)],$$

$$\sin x \cos y = \tfrac{1}{2}[\sin(x + y) + \sin(x - y)],$$

$$\cos x \sin y = \tfrac{1}{2}[\sin(x + y) - \sin(x - y)],$$

$$\cos x \cos y = \tfrac{1}{2}[\cos(x + y) + \cos(x - y)].$$

Functions of Twice an Angle. —

$$\sin 2x = 2 \sin x \cos x, \qquad \cos 2x = \cos^2 x - \sin^2 x,$$

$$\tan 2x = \frac{2 \tan x}{1 - \tan^2 x}.$$

Functions of Half an Angle. —

$$\sin \frac{x}{2} = \sqrt{\frac{1 - \cos x}{2}}, \qquad \cos \frac{x}{2} = \sqrt{\frac{1 + \cos x}{2}}, \qquad \tan \frac{x}{2} = \sqrt{\frac{1 - \cos x}{1 + \cos x}}.$$

Functions of Three Times an Angle. —

$$\sin 3x = 3 \sin x - 4 \sin^3 x, \qquad \cos 3x = 4 \cos^3 x - 3 \cos x,$$

$$\tan 3x = \frac{3 \tan x - \tan^3 x}{1 - 3 \tan^2 x}.$$

[W. A. Del Mar.]

TRIGONOMETRY. — (*See also Trigonometric Functions.*) Any triangle is completely defined when, (1) two sides and the included angle are known, (2) one side and two angles are known, (3) three sides are known. Let the sides and angles of a triangle be designated as in Fig. 1.

1. Given two sides a **and** b**, and the included angle** γ**.** Then

$$c = \sqrt{a^2 + b^2 - 2\,ab\cos\gamma}$$

$$\sin\alpha = \frac{a}{c}\sin\gamma$$

$$\beta = 180 - \alpha - \gamma.$$

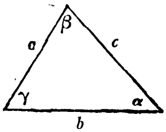

Fig. 1.

2. Given the side a **and the two angles** β **and** γ**.** Then

$$\alpha = 180 - \beta - \gamma$$

$$b = a\frac{\sin\beta}{\sin\alpha}$$

$$c = a\frac{\sin\gamma}{\sin\alpha}.$$

3. Given the three sides a**,** b **and** c**.** Put

$$s = \tfrac{1}{2}(a+b+c)$$

Then

$$\sin\alpha = \frac{2}{bc}\sqrt{s(s-a)(s-b)(s-c)}$$

$$\sin\beta = \frac{b}{a}\sin\alpha$$

$$\gamma = 180 - \alpha - \beta.$$

Relations Between Sides and Angles. — The following relations between the sides and angles of a triangle are sometimes useful:

$$\frac{a}{\sin\alpha} = \frac{b}{\sin\beta} = \frac{c}{\sin\gamma}$$

$$\cos\alpha = \frac{b^2 + c^2 - a^2}{2\,bc}$$

$$\sin\frac{\alpha}{2} = \sqrt{\frac{(s-b)(s-c)}{bc}}$$

$$\cos\frac{\alpha}{2} = \sqrt{\frac{s(s-a)}{bc}}$$

and similar relations for the other two angles.

[W. A. Del Mar.]

TROLLEY SYSTEMS, OVERHEAD. — (*See also Cars, Electric; Cross Arms; Locomotives, Electric; Poles for Overhead Lines; Rails, Track and Third; Railways, Electric, Traction Systems for; Railways, Location and Permanent Way for; Third-rail Systems; Transmission Lines; Trolley Systems, Underground; Wires and Cables, Bare.*) The following is a brief table of contents of this article:

The trolley wire is usually of hard-drawn copper but sometimes of steel, which is suspended from insulators some 16 to 30 feet above the ground, and presents a continuous contact surface to a trolley wheel or bow attached to the rolling stock. There are two classes of trolley construction, the span wire and the side bracket; each may have either simple or catenary suspension.

Span-wire and Side-bracket Construction. — In the simple span wire construction the trolley wire is supported by wires stretched across the tracks between poles or building walls. The side-bracket construction resembles the span wire except that instead of the supporting wire being stretched between two poles, it is stretched between two supports on the same pole. In both of these types of construction, the trolley wire is supported at intervals of 100 feet or more and sags considerably between supports, making it necessary for the trolley to be in constant vertical vibration as the cars move.

Catenary Construction. — The speed attained upon modern electric roads makes it difficult to obtain satisfactory service with a trolley wire which dips between each support and sags and sways with every impulse. The catenary construction was devised to meet this condition. In general, it consists of a grooved copper trolley wire suspended horizontally from a sagging messenger cable, which is suitably insulated and firmly held in place. The supporting structure preferably employed for interurban single- or double-track roads is of the side-bracket type, but for some conditions cross-span construction becomes necessary. The latter method of support differs only in the substitution of a catenary cross span for the bracket arm and doubling the number of poles required for single track.

APPLICATIONS OF VARIOUS TYPES OF CONSTRUCTION. — The overhead trolley system is used on urban railways, wherever the unsightliness or danger of its exposed construction is not considered objectionable. It is used on interurban and suburban lines wherever the current taken by the trains is not too great to be economically carried on copper wires. In recent years it has been used in conjunction with the alternating-current systems of electric traction on electric trunk lines.

Center-pole construction is the most sightly for double-track city railways, especially if ornamental brackets are used, side-pole construction being generally used for single-track lines. Span-wire construction is used where, for any reason, it is impracticable to have the poles near the tracks or where, as is commonly the case in Europe, the span wires are supported from the walls of buildings. Prejudice against overhead lines is often due to the excessive loading of poles, which is both unsightly and dangerous.

ELECTRICAL DESIGN OF CONDUCTORS. — In designing the trolley system careful attention must be given to both the electrical and mechanical features. In this section will be treated the electrical features, and in the following section the mechanical features. The electrical design of railway distribution systems involves the consideration of potential drop, heating of conductors and feeder economy. The heating of conductors is seldom an important factor in railway feeder design, as it is usually necessary to use a low current density to keep down the drop of potential. A discussion of the heating of conductors will be found under *Wires and Cables, Bare.* The feeder system being sufficient to meet the conditions imposed by the allowable potential drop (*see below*), it will be economical to make it greater if the saving in the cost of energy which will result, is greater than the increase in interest and other charges on the additional investment.

Allowable Potential Drop. — The total potential drop is limited by the necessity of running the cars at a certain speed and by the need of keeping the car lights brilliant. The potential drop in the ground conductors, i.e., the track rails and bare negative feeders, is further limited by the danger of electrolysis by current leaking into the earth (*see article on Electrolysis*).

The drop in the grounded conductors under maximum-load conditions is limited by law in Great Britain to 7 volts between any two points of the system. In Germany the maximum drop in the grounded conductors is limited to 1 volt per kilometer (1.61 volts per mile). In the United States the legal limit is a matter of local option and is, in general, less severe than in Europe.

Calculation of Potential Drop. — The method of calculation of potential drop depends upon the following conditions: (1) whether the current is direct or alternating; (2) whether the load is concentrated at one point, sparsely distributed or evenly distributed; (3) the distribution of metal in the feeder circuits, and (4) whether the section is being fed by one or by two or more substations. Calculations for alternating-current lines differ from those for direct-current lines only in taking into account the inductance, as described below. On city railways it is usual to assume the load to be evenly distributed, it being stated as a given number of amperes per foot (*see article on Railways, Energy Requirements and Motor Capacity for*). If the load is actually concentrated at n equidistant points, the drop will exceed that calculated on the assumption of uniform distribution by about $\frac{100}{n}$ per cent. On interurban and trunk lines, the cars are usually concentrated at one or two points between substations, making the assumption of uniform distribution impracticable. In such cases the loads should be located so as to give the worst conditions, and calculations made as for any network.

Where electrolytic damage is to be guarded against, the drop of potential in the track rails themselves has to be calculated, as well as the total drop in the rails and feeders.

Resistance of Trolley and Track. — Values of the resistance of trolley wires to direct current will be found in the article on *Wires and Cables, Bare,* and values of the resistance of rails to direct current will be found in the article on *Rails, Steel.* It should be noted that the resistances of the trolley and positive feeders are in parallel and that the track rails and negative feeders are in parallel. Also note that in the case of high-voltage systems a considerable portion of the current returns through the earth and not through the rails, and consequently the drop in the rails is due only to that part of the current which returns through them. For preliminary calculations, however, the full current may be assumed as returning through the rails.

Formulas for Direct-current Trolley Circuits. — The following formulas apply to certain typical circuits which frequently occur in practice. Let

I = total current in amperes taken by all cars on section considered,
L = total length of section in 1000 feet,
V_p = total drop in volts, in positive conductors between substation bus and far end of line,
V_n = total drop in volts in negative conductors between substation bus and far end of line,
$V = V_p + V_n$ = total drop in volts in both positive and negative conductors,
r_p = resistance in ohms of all the positive conductors in multiple per 1000 feet of line,
r_n = resistance in ohms of all the negative conductors in multiple per 1000 feet of line,
$r = r_p + r_n$ = total resistance in ohms per 1000 feet of line,
l = distance in 1000 feet, from far end of line to any point P,
v = drop to the point P, subscripts used as for V.

Uniformly Distributed Load, Uniform Conductor, Fed from One Substation. — Then

$$v = \frac{rIl^2}{2L},$$

$$V = \frac{rIL}{2}.$$

These formulas are applicable to either the positive or negative conductors considered separately or to both in series.

Uniformly Distributed Load, Conductor Tapered to give Minimum Weight of Metal, Fed from One Substation. — For minimum weight the tapering must be such that at any point P

$$r = \frac{3V}{2I\sqrt{L}\sqrt{l}},$$

i.e., the cross-section, if all the conductors are of the same metal, must increase directly as the square root of l. The drop to the point P is

$$v = \frac{V\sqrt{l^3}}{L^3}.$$

These formulas also apply to either the positive or negative conductors separately or to both in series.

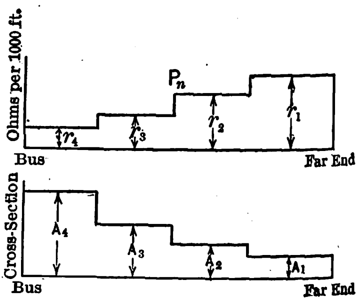

Fig. 1.

Uniformly Distributed Load, Conductor Divided into Sections (Fig. 1); Each Section of Constant Resistance, Fed from One Substation. — The drop from P_n to the far end of line is

$$\frac{I}{2L}\sum_{n=1}^{n=n} r_n[L^2{}_n - L^2{}_{(n-1)}].$$

This formula is applicable to either the positive or negative conductors.

Concentrated Load, Section Fed from One End.—Fig. 2 shows a 4-track road with 4 trolley wires and 3 feeders with the tracks cross-bonded at intervals. The solution given below is a general one, and may be applied to any case from 1 track and 1 trolley wire up. Let all distances be expressed in 1000 feet and let

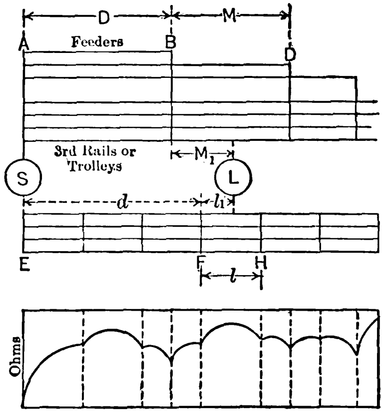

Fig. 2.

N_f = number of feeders in section considered, e.g., for the section AB, $N_f = 3$, and for the section BD, $N_f = 2$,

N_c = number of contact conductors, trolley wires or third rails in section considered, e.g., four are shown in Fig. 2,

N_t = number of tracks in section considered,

R_f = resistance of each feeder per 1000 feet,

R_c = resistance of each contact conductor per 1000 feet,

R_t = resistance of each track per 1000 feet (1 rail or 2 rails in multiple depending upon whether 1 or 2 rails are used for return conductor),

$n = N_c + \frac{R_c}{R_f} N_f$ for the section considered.

Then for the section in which the load may be, the resistance of the positive conductors from the load to the end of that section in the direction of the substation, e.g., the resistance from L to B, is

$$R_c M_1 \left[1 - \frac{(n-1) M_1}{nM} \right].$$

The resistance of the positive conductors in any section such as BA is

$$\frac{R_c D}{n}.$$

(Note that the value of n for this section is not the same as for the section BD.)

The resistance of the negative conductors from the load to the first cross bond in the direction of the substation, e.g., the resistance from L to F, is

$$R_t l_1 \left[1 - \frac{(N_t - 1) l_1}{N_t l} \right].$$

The resistance of the remaining portion of the negative conductors, e.g., from F to E, is

$$\frac{R_t d}{N_t}.$$

(Note that if negative feeders are used, each negative feeder having a resistance of R_f' per 1000 feet, then for N_t in the last two formulas substitute $n' = N_t + \frac{R_t}{R_f'} N_f'$, where N_f' is the number of negative feeders for that section.)

The total resistance from the load to the substation is the sum of the resistances as above calculated.

Concentrated Load, Section Fed from Both Ends, Substation Voltage at the Two Ends the Same.—The most convenient method of treating such problems is to plot an "equivalent-resistance-distance" curve such as shown in Figs. 2 to 5. By "equivalent resistance" is here meant that resistance by which the total current taken by the load must be multiplied to give the total drop in voltage between the load and either substation. For example, if the substation voltage is 600 at each end, the voltage across the load is 550 and the current taken by the load is 200 amperes, then the equivalent resistance is $R = \dfrac{600-550}{200} = 0.25$. This method avoids the determination of the distribution of the current in the various parts of the network, and the resistance when once determined can be applied to any load.

1. In Fig. 3 is shown a single track and single trolley. S_1 and S_2 are substations; L is a load placed arbitrarily between corresponding points P_1 and P_2 on the positive and negative conductors respectively. Let

a = resistance of the conductors between the points $S_1P_1P_2S_1$;

b = resistance of the conductors between the points $S_2P_1P_2S_2$.

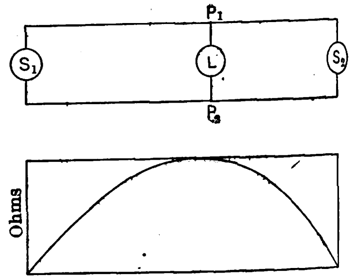

Fig. 3.

These resistances are the resistances of the transmitting conductors and do not include the internal resistances of the substations and load. Then the equivalent resistance is

$$R = \frac{ab}{a+b}.$$

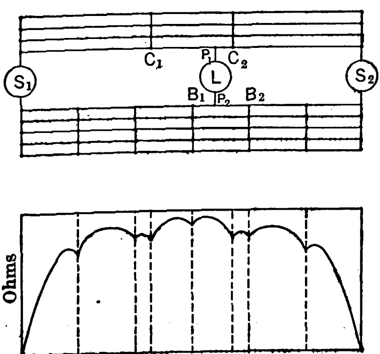

Fig. 4.

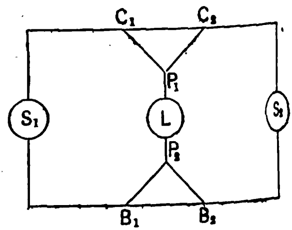

Fig. 4a.

2. In Fig. 4 is shown a 4-track road with 4 trolleys, both track and trolley cross-bonded. Fig. 4a is a simplified diagram of Fig. 4, corresponding points being designated by identical letters.

S_1 and S_2 are substations; L is a load placed arbitrarily between points P_1, on the positive system and P_2 on the negative system; C_1 and C_2 are ties between positive conductors and B_1 and B_2 ties between negative conductors.

Let

a = resistance of loop $S_1C_1P_1LP_2B_1S_1$,
b = resistance of loop $C_1P_1C_2C_1$,
c = resistance of contact conductor C_1P_1,
d = resistance of contact conductor C_2P_1,
e = resistance of loop $B_1P_2B_2B_1$,
f = resistance of track B_1P_2,
g = resistance of track B_2P_2,
h = resistance $\frac{d^2}{b} + \frac{g^2}{e}$,
i = resistance $\frac{c^2}{b} + \frac{f^2}{e}$,
j = resistance $S_2C_2P_1LP_2B_2S_2$.

These resistances are the resistances of the transmitting conductors and do not include the internal resistances of the substations and load. The equivalent resistance is

$$R = \frac{aj - ah - ji - 2\left(\frac{fg}{e} \times \frac{cd}{b}\right) + \frac{f^2d^2 + c^2g^2}{eb}}{a + j - h - i - 2\left(\frac{fg}{e} + \frac{cd}{b}\right)}.$$

Concentrated Load, Section Fed by Feeders from Both Ends. — Fig. 5 shows a simple case with feeders for the positive conductors only. No general formula is available for such a circuit. Any such network can, however, be calculated by Kirchhoff's Laws (q.v.), using the numerical values of the resistances for the various resistances. The equivalent resistance from the substations to the load is then the drop in voltage for a load of one ampere.

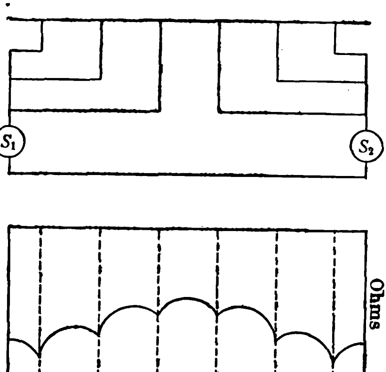

Fig. 5.

Ways of Reducing Total Drop. — Three methods are employed for reducing the total drop in the trolley and rails, viz:

1. Plain or "Non-boosted" Feeders. — Copper feeders, usually bare, may be connected to the trolley wire, third rail or track rails at frequent intervals. If the resistance of the trolley is high compared with that of the rails, which is usually the case, the feeders should be used to reënforce the trolley wire and not the track. In general, the most economical use of additional copper is to connect it in parallel with that side of the circuit having initially the higher resistance.

2. Boosted Feeders. — An insulated feeder may be tapped into the trolley wire or third rail at one point, and connected to a booster at the substa-

tion. The principle of this method is to increase the activity of the feeder, i.e., to make it carry more current and thereby reduce the current in the trolley wire. This is necessary only where the resistance of the line is so low that a moderate-sized feeder does not take its full share of current. It is not much used because if the line resistance is already low and the load is small, the drop will usually be small enough naturally, and if the load is great, the booster and feeder will usually have to be so large in order to produce any effect, as to be prohibitive in first cost and cost of operation.

3. **Floating Battery,** i.e., a battery connected across the line so as to charge when the line potential is high and discharge when it is low. This scheme is very little used on account of the high cost of operating and maintaining a battery. It is difficult to imagine under what conditions such a system would be commercially practicable, but if anywhere, it would be on a long line with light load and small feeders. Typical calculations for floating batteries are given in Lyndon's *Storage Battery Engineering*, Chap. XLIV.

Ways of Reducing Drop in the Negative Side of Circuit.—Owing to the necessity of preventing the leakage of current from track rails into the earth, it may be necessary to reduce, not the total drop in the negative system, but the drop in the grounded portion of the negative. This may be accomplished by the use of insulated feeders connected to the track rails so as to drain the current from the latter and thus reduce the drop in the rails, regardless of the drop in the feeders themselves. Such feeders may be used with or without a booster. Used with boosters, this method is probably the most economical way of reducing the drop in return rails where a large reduction is necessary to prevent electrolysis.

Negative Feeder with Booster.—In the case where the load is uniformly distributed over the line, the size of booster which must be installed in the substation may be determined as follows:

Let a = amperes entering negative feeder system per foot of line,

r = resistance of negative feeder system per foot,

R = total resistance of the feeder connecting the booster to the negative feeder system,

I = total amperes entering negative feeder system from the motors,

I_0 = amperes to be taken off by booster,

$l = \dfrac{I - I_0}{a}$ = distance from substation to the point at which the current in the negative feeders is to be zero,

l_1 = distance from booster tap to point in negative feeders where current is zero,

l_2 = the distance from the booster to the end of the line.

Then the booster voltage is

$$RI_0 - \tfrac{1}{2}\,ar(l^2 - l_1^2).$$

The output of the booster is, of course, the product of the current and voltage. The total drop is

$$\tfrac{1}{2}\,ar(l^2 - l_1^2 + l_2^2).$$

See Del Mar's *Electric Power Conductors*, Chap. V, for a more complete treatment.

Formulas and Constants for Alternating Current Trolley Circuits.—Little information is available on the effective or a-c. resistance (*see Alternating Currents*) and reactance of steel rails. As a rough approximation the a-c. resistance of a rail at 25 cycles per second may be taken as 5 times its d-c. resistance and the reactance of the rail as approximately the same as that of one wire of a pair of No. 0000 wires at a distance apart equal to the height of the

trolley wire above the track, i.e., roughly as 0.4 ohm per mile. As a matter of fact the a-c. resistance depends upon the shape of the rail, its magnetic quality, the value of the current and the frequency; to a lesser extent the inductance, and therefore the reactance, depends upon these same items.

Data from Tests on N. Y., N. H. & H. R.R. — The most reliable data available are those obtained by A. W. Copley from tests on the New York, New Haven and Hartford Railroad and reported in the Trans. A.I.E E., 1908, Vol. 27(2) p. 1171. An analysis of these tests is also given by H. Pender in the Elec. World, 1909, Vol. 53, p. 1457. Copley's results showed that a considerable portion of the current entering the track from the load leaked to the earth. The combined resistance r of any number of trolley wires, and track rails and earth, as determined by Copley, can be represented by the following formula

$$r = \frac{p_1 r_1 + p_2 r_2}{100},$$

where r_1 = the resistance of each trolley wire separately, p_1 = the per cent of the total current in this wire, r_2 = the a-c. resistance of each rail separately and p_2 = the per cent of the total current in this rail. Similarly, the combined reactance x of any number of trolley wires and track rails and earth return can be represented approximately by the formula

$$x = \frac{p_1 x_1 + p_2 x_2}{100},$$

where x_1 = the reactance of a given trolley wire, x_2 = the reactance of a given rail and p_1 and p_2 as above.

Pender gives the following values for trolley wire and rail separately, based upon Copley's tests:

Item	Resistance, ohms per mile		Reactance,* ohms per mile	
	25 cycles	15 cycles	25 cycles	15 cycles
Single trolley wire, No. 0000 B. & S....	0.26	0.26	0.38	0.23
000 B. & S....	0.33	0.33	0.38	0.23
00 B. & S....	0.42	0.42	0.39	0.23
Single rail, 100 pounds to the yard.....	0.16	0.13	0.44	0.26

* For the trolley wire 25 ft. above the track, changing the height of the trolley wire 5 ft. up or down changes these values by less than 5 per cent.

The combined resistance and reactance respectively of the trolley wires, rails and earth are given in the following table:

For any other weight of rail the a-c. resistance of the rail itself may be taken as roughly inversely proportional to the weight per yard. The reactance of the rail, however, is practically independent of its cross-section, for the magnetic flux within the rail is relatively small compared with the total flux surrounding the rail (*see Inductance*).

Formulas for Single-phase Calculations. — The calculation of the power lost and drop in voltage between a load and the power house are calculated in the same manner as in the case of an ordinary single-phase a-c. trans-

RESISTANCE AND REACTANCE PER MILE OF ROAD

100-pound Rails

Number of tracks	....		1		2		4	
Number of trolley wires	1		1		2		4	
Number of rails	1		2		4		8	
Per cent of total current returning through rails†	25		40*		58*		75*	
Cycles per second	25	15	25	15	25	15	25	15
Combined resistance of trolley wires, track and earth per mile of road								
No. 0000 B. & S. trolley	0.30	0.29	0.29*	0.28*	0.16*	0.15*	0.086*	0.082*
000 B. & S. trolley	0.37	0.36	0.36	0.35	0.20	0.19	0.11	0.10
00 B. & S. trolley	0.46	0.45	0.45	0.44	0.24	0.23	0.13	0.12
Combined reactance of trolley wires, track and earth per mile of road, all three sizes of trolley wire	0.49	0.30	0.47*	0.28*	0.27*	0.16*	0.17*	0.10*

* The figures marked thus * are taken directly from the paper by Copley, whose tests were confined to No. 0000 trolley wires; the other values are calculated by Pender.

† The percentages of total current returning through the rails are test results on the N.Y., N.H. & H.R.R., and refer to relatively long sections (over 3 miles); a greater proportion of current flows in the rails in the immediate vicinity of the load and power house. The proportion of the total current which will return through the earth will depend upon the nature of the soil and ballast; for any other division of current the resistance and reactance can be obtained from the approximate formulas given above.

mission line (*see Transmission Lines*). For a concentrated load (e.g., a single train) the calculation is as follows: Let

V = volts between trolley wire and track;
P = kilowatts at the locomotive delivered to locomotive;
$\cos\phi$ = power factor of load taken by locomotive;
l = distance in miles, between power house and locomotive;
r = combined resistance in ohms, per mile of trolley wire, rails and earth return;
x = combined reactance, in ohms, per mile of trolley wire, rails and earth returns;
$R = rl$;
$X = xl$.

Then the current taken by the locomotive is

$$I = \frac{1000\,P}{V\cos\phi} \quad \text{amperes,}$$

the power lost is

$$p = \frac{RI^2}{1000} \quad \text{kilowatts,}$$

the drop in voltage between the power house and locomotive is

$$v = \sqrt{(V\cos\phi + RI)^2 + (V\sin\phi + XI)^2} - V \quad \text{volts,}$$

and the power factor at the power house is

$$\cos\phi_0 = \frac{1000\,(P + p)}{I\,(V + v)}.$$

Example. — 2000 kw. at 25 cycles per second are to be supplied to a locomotive at 90 per cent power factor and 10,000 volts at a distance of 20 miles from the power house. The circuit consists of a No. 0000 trolley wire and two 100-lb. track rails. Then $V = 10{,}000$, $P = 2000$, $\cos\phi = 0.9$, $\sin\phi = 0.435$, $l = 20$, $r = 0.29$ (assuming only 40 per cent of the current returning through the rails), $x = 0.47$ (same assumption), $R = 0.29 \times 20 = 5.8$, $X = 0.47 \times 20 = 9.4$. Whence

$$I = \frac{1000 \times 2000}{10{,}000 \times 0.9} = 222 \text{ amperes},$$

$$p = \frac{5.8 \times (222)^2}{1000} = 286 \text{ kilowatts},$$

$$v = \sqrt{(10{,}000 \times 0.9 + 5.8 \times 222)^2 + (10{,}000 \times 0.435 + 9.4 \times 222)^2} - 10{,}000 = 2130 \text{ volts},$$

$$\cos\phi_0 = \frac{1000\,(2000 + 286)}{222\,(10{,}000 + 2130)} = 0.848.$$

Scheme of Connections Used by N.Y., N.H. & H.R.R. — The distribution system is shown diagrammatically in Fig. 6 where A is the trolley

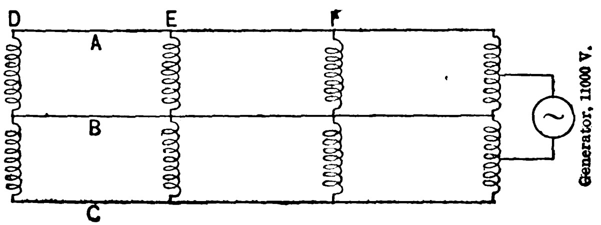

Fig. 6.

wires, B the track rails and C a feeder. These three sets of conductors are connected at intervals of about two miles through auto-transformers D, E and F. The difference of potential between A and B, and between B and C is 11,000 volts and between A and C is 22,000 volts. The effect of this arrangement is to practically give a transmission voltage of 22,000 with 11,000 volts at the trolley, and to greatly reduce the current in the grounded conductors with consequent reduction of disturbances to telephone lines.

MECHANICAL DESIGN OF OVERHEAD SYSTEM. — The various parts of the overhead system will first be described, and then the various types of construction, span wire, catenary, etc.

Parts of Overhead Trolley Construction. — The trolley wire is secured to an "ear" by soldering, clamps or other means, the ear is bolted to a "suspension" which may or may not be provided with an insulating portion. These suspensions are carried by span wires which in turn are fastened to the poles or brackets, or may be fastened directly to the bracket. If the "ear" is not insulated, "strain" insulators are inserted in the span wire between the ear and its point of attachment to the poles or brackets. A slightly different form of suspension, called a "pull-off," is used on curves. At turnouts "trolley frogs" must be used to guide the trolley wheel. These various parts are illustrated in the accompanying cuts.

Trolley Ears. — Figs. 7 to 10 are for round wire. Fig. 7 shows an ear with flaps, which are bent around the wire to hold it in place; this type is seldom

Fig. 7.

Fig. 8.

Fig. 9.

Fig. 10.

Fig. 11.

Types of Trolley Ears for Round Wire

used on account of arcing at the flaps. The ear shown in Fig. 8, which has a deep groove into which the wire is soldered, is the type in common use. These ears may be provided with rings as in Fig. 9 to which guy wires are attached to relieve the strain at curves and for steadying the line at intervals. Fig. 10 shows the type of ear used at points where the trolley is spliced, which should always be at an ear. Fig. 11 shows an ear with a terminal for a feeder connection.

Figs. 12 to 14 are designed for grooved or figure "8" trolley wire. Special

Fig. 12.

Fig. 13.

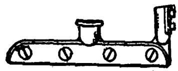

Fig. 14.

Types of Trolley Ears for Figure "8" Wires

grooved or figure-8 wire affords a smoother running surface for the trolley wheel or bow as the ear only grips the upper part, leaving the lower part absolutely even. This construction is practically essential for bow trolleys.

Soldering Trolley Wire to Ears. — The strain should be taken off the wire by a U-shaped clamp catching hold of it on each side of the ear. The soldering iron should weigh about 8 or 9 pounds, and should have a groove fitting half way round the wire. Special precautions should be taken not to have the iron unnecessarily hot.

Suspensions for Straight Line Work. — Fig. 15 shows an uninsulated suspension with ear attached for straight line work. Fig. 16 shows a suspension with strain insulators at each end; this is also used on curves for double-track

Fig. 15.

Fig. 16.

Fig. 17.

Fig. 18.

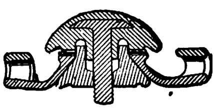

Fig. 19.

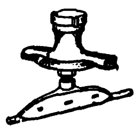

Fig. 20.

Types of Suspensions

work. Figs. 17 and 18 show solid insulated suspensions for span wire and side-bracket construction, respectively. These types are frequently used, and are quite satisfactory if the insulating material used in their construction is properly made. Fig. 19 shows a section of an assembled cap and cone suspension. Fig. 20 shows a cap and cone suspension with ear attached. The cap and cone are made separate. This type is preferred by some engineers on account of the

possibility of replacing injured bolts and insulation without removing the whole suspension. This advantage is partly offset by the greater liability to trouble due to multiplicity of parts.

Strain Insulators. — Fig. 21 shows a "globe" strain insulator, the type most commonly used. Fig. 22 shows a "Brooklyn" strain insulator. This type is used on wooden pole and light iron pole construction to draw span wires taut. It is also required even for heavy iron pole construction if spans are long and temperature variation great. Bolts may be provided at both ends if an extra amount of adjustment is required. A globe strain and a Brooklyn strain may be used in series where extra insulation is required.

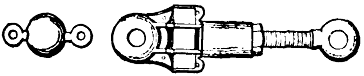

Fig. 21. Fig. 22.
Strain Insulators

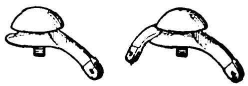

Fig. 23. Fig. 24.
Pull-offs

Pull-offs. — Fig. 23 shows a cap and cone pull-off for single-curve construction and Fig. 24 a cap and cone pull-off for double-track-curve construction. Pull-offs of the same type as the uninsulated and solid insulated suspension shown in Figs. 15, 17 and 18 are also used.

Trolley Frogs. — A trolley frog is a malleable iron casting used at switches or crossovers where trolley wires from different tracks unite. Its function is to hold the diverging wires together and afford a smooth running path to the trolley wheel when a car passes or enters a switch. A common type is illustrated in Fig. 25. Frogs are made for various angles of divergence, and both right and left handed. The usual angles are 8, 15 and 20 degrees.

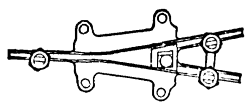

Fig. 25. Trolley Frog

Sag and Tension in Overhead System. — Particular attention must be paid to designing the overhead structure in such a manner that it will safely stand the extra tension due to the contraction of the wires at low temperatures and the extra loads due to wind and sleet, and a sufficient allowance should be made in the height of the trolley wire to take care of the extra sag which it experiences at high temperatures. With a simple trolley construction the variations in tension and sag may be calculated by a direct application of the rules given in the article on *Transmission Lines;* in the case of catenary construction, the additional load due to trolley wire, clips, etc., is treated in the same way as a sleet or wind load.

Direct Suspension. — The following discussion applies primarily to span-wire and side-bracket construction; catenary construction is treated in a separate section below. Modern practice regarding the dimensions of poles, size of trolley and span wire, height of trolley wire, etc., is illustrated in Tables I and II.

Height of Trolley Wire Above Rail. — The height of wire varies between a minimum of 16 feet and a maximum of 22 feet, the usual height being about 18 feet. It is usual to raise the wire at railroad crossings to a height of 22 feet or more.

Rake of Poles. — Bracket-arm poles on tangent construction should have a rake backwards not exceeding 3 inches, and span-wire poles in hard ground a rake of from 4 to 5 inches. In soft ground a rake of 12 inches is not uncommon. Center poles should be set vertically except at curves, where they should bend away from the curve along the perpendicular to the tangent at that point of the curve.

Anchorage. — At both ends of every grade and curve, there should be a permanent anchorage. If there are not many grades and curves, anchorages should be provided at intervals of from ¼ to ¾ of a mile. An anchorage is made by means of a steel cable running from the trolley wire to one or more anchor poles through an anchor ear and strain insulators.

Curves. — At curves in the track the trolley wire should be made to follow the curve by means of pull-offs or wires pulling the trolley wire outward

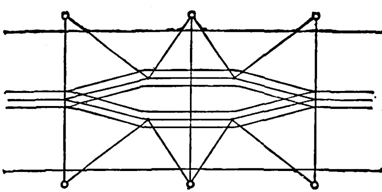

Fig. 26. Simple Pull-off Arrangement

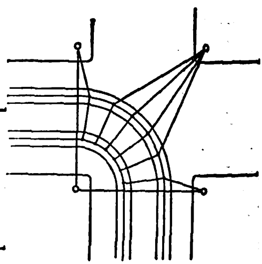

Fig. 27. Simple Pull-off Arrangement

as shown in Figs. 26 and 27.

Wherever possible the pull-off wires should be radial to the trolley wire. This, however, requires a large number of poles, and is therefore impracticable in cities. In such cases, the bridle, bow-string or backbone construction shown in Figs. 28, 29, and 30 is resorted to. In this construction the pull-off wires

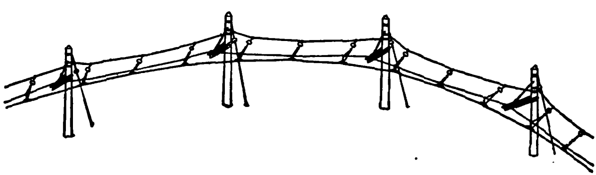

Fig. 28. Bridle Construction at Curve

instead of being anchored to individual poles are fastened to a wire which is stretched between poles. While this construction is almost universally used in cities, it is more expensive to maintain than single pull-offs, and is therefore less favored for interurban lines.

A combination of the two types of construction is shown in Fig. 31. Figs. 28 to 31 are from G. E. Co. publications.

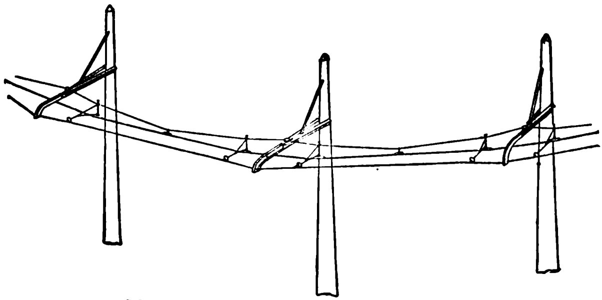

Fig. 29. Bow-string Construction at Curve

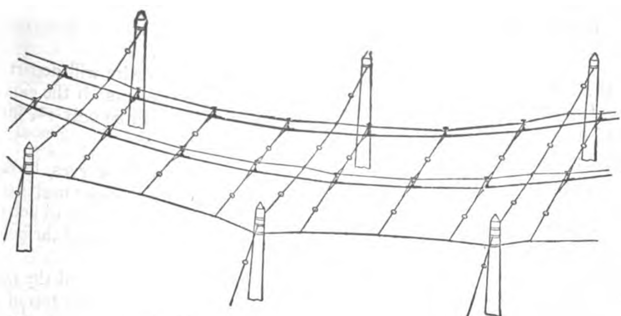

Fig. 30. Backbone Construction at Curve

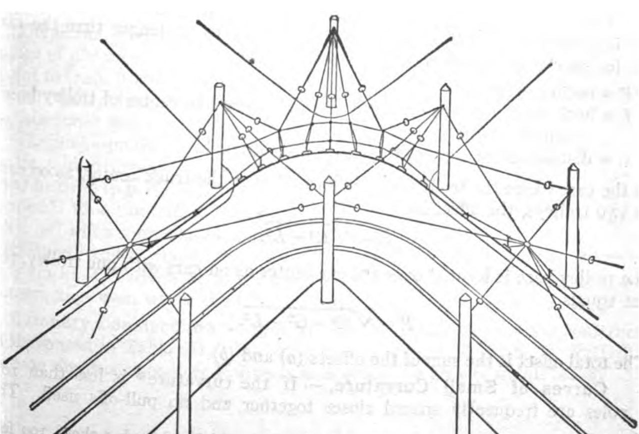

Fig. 31. Combination Construction at Curve

Spacing of Pull-offs at Curves. — The number of pull-offs should be sufficient to keep the wire within about 2½ inches from the theoretical curve. This may be accomplished by spacing the successive ears in accordance with the following relations:

Let L = distance between pull-offs in feet,
R = radius of curve in feet,
a = offset of wire in inches from theoretical curve, midway between pull-offs, the ears being assumed to lie on the theoretical curve.

Then,

$$L = \sqrt{\frac{2aR}{3} - \left(\frac{a}{6}\right)^2},$$

or

$$L = 0.815\sqrt{aR},$$

with an error less than ¼ per cent for all radii greater than 40 feet.

If a is to be 2½ inches, then

$$L = 1.29\sqrt{R} \text{ approximately.}$$

If the ears are set exactly on the theoretical curve, the wire will depart 2½ inches from the correct position half way between the two ears; if the ears are set 1¼ inches from the curve, the mid-point of the wire will be only 1¼ inches when L is taken equal to $1.29\sqrt{R}$.

Offset of Trolley Wire at Curves. — It is usual, at curves, to offset the trolley wire from the center of the track (a) because the trolley wheel is tilted inward due to the elevation of the outer rail, and (b) because in order to keep the wheel on the wire, the latter must be so placed that the projection of the pole on the plane of the track is always tangential to the wire.

(a). The former offset, measured horizontally toward the inside of the curve, equals $h \tan \theta$, where h is the normal height of the wire above the top of rail, and θ is the angle of elevation between the plane of the track and the horizontal. For standard gauge and wire 18 feet above the top of rail this offset is about 4 inches for every inch of elevation.

(b). The latter offset, also measured horizontally toward the center of the curve, is calculated as follows, assuming the curve to be longer than the car itself; for shorter curves the offset will be less. Let

R = radius of curve,
L = horizontal distance of center of trolley wheel to center of trolley base, usually about 11 feet,
G = distance from center of car to center of truck.

In the case where the trolley base is located over the truck center, as on cars with two trolleys, the offset is

$$R - \sqrt{R^2 - L^2}.$$

If the trolley base is located over the car center as on cars with one trolley, the offset equals

$$R - \sqrt{R^2 - G^2 - L^2}.$$

The total offset is the sum of the offsets (a) and (b).

Curves of Small Curvature. — If the curvature* is less than 10°, the poles are frequently spaced closer together and no pull-offs used. The

* The degree of curvature of a track is the angle which subtends a chord 100 feet long, between points on the center line of the track.

following table gives the practice of the Denver and Interurban R.R. Co., which may be considered typical, the divergence of the wire from the theoretical curve being kept within 3½ inches.

SPACING OF POLES ON CURVES, INTERURBAN ROAD

Degree of curvature of track	Pole spacing, feet	Divergence of trolley wire from track center, inches	Degree of curvature of track	Pole spacing, feet	Divergence of trolley wire from track center, inches
Tangent	120	0	6	60	2.87
1	120	1.87	7	50	2.34
2	110	3.37	8	50	2.64
3	90	3.06	9	50	2.94
4	80	3.37	10	50	3.24
5	70	3.06			

Turnouts. — (*See also Railways, Location and Permanent Way for.*) The location of the trolley frog at turnouts may be determined as follows. Referring to Fig. 32, from switch point *A* draw a line to center point *D* of track frog distance *BC* and from switch point *B* draw a line to center point *E* of arc *AEC*. The intersection of these two lines at *F* will be the proper location of the frog. While certain variables, such as superelevation of the outer rail on the curve, length of wheel base and projection of trolley pole rearward from center of car, may necessitate slight variation of setting, this location will be found so nearly correct that a very small alteration, which must be determined by experiment, will compensate for the variable conditions.

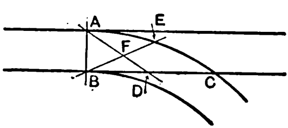

Fig. 32.

The accompanying table gives the range of distance from track switch point to track frog with which each set of trolley frogs may be most satisfactorily used:

Track-frog distance	Divergence angle of trolley frog
Up to 22 feet..............	20°
From 20 to 30 feet.........	15°
Above 28 feet..............	8°

The minimum frog distance given in the table with which the 15° frogs may be used to best advantage corresponds to a turnout radius of 40 feet, but when suburban cars, using high-speed trolley wheels, run over city tracks it is advisable to use 15° rather than 20° frogs throughout the city construction even where the minimum frog distance is less than 20 feet.

Catenary Construction. — Modern practice regarding catenary construction is illustrated in Table III. The construction on the N. Y., N. H. & H. R.R., and on the Austrian State Railways is described in greater detail below.

TABLE III. — DETAILS OF TRUNK & INTERURBAN RAILWAY CONSTRUCTION. CATENARY SUSPENSION.

(Messenger cables composed of 7 strands in all cases.)

Simple and Compound Catenary Construction. — Catenary constructions may be divided into simple and compound. In the former the trolley wire or wires are carried by one or two messenger cables which are supported only at the poles, bents or span wires; in the latter, the horizontal wire or wires are carried by a messenger cable, which is itself suspended from another messenger cable which is supported at the poles, bents or span wires. The advantages of the compound catenary are greater flexibility, reduced stresses in the supporting wires, shorter hangers, better lightning protection and superior curve construction. (*See description of N. Y., N. H. & H. R.R., construction below.*) The simple catenary is sometimes made with two messenger cables from which the horizontal wire or wires are suspended by triangular frames.

To obtain a line which will not require frequent readjustment, the messenger cable must be installed with practically uniform tension throughout its length, making it necessary to have less sag in the shorter spans. For this reason certain definite pole spacings and corresponding hanger lengths have been standardized (*see next section below*).

Suspensions. — (*See also p. 1738.*) The number of suspensions depends upon the speed at which the cars are to be run, and upon whether a bow or wheel trolley is used. The three-point suspension in which, with 150 feet spacing, the hangers are 50 feet apart has been found ample for wheel collectors at speeds up to 65 m.p.h. With the sliding pantagraph or bow trolley an eleven-point suspension has been found sufficient, with 150 feet pole spacing.

Hangers. — (*See also p. 1739.*) Where only one horizontal wire is suspended from the messenger cable, the hangers should hang loosely from the cable and should be screwed fast to the trolley wire. This permits the trolley wire to rise slightly as the trolley passes under it, thereby making the wire equally flexible along its entire length. Where a steel contact wire is clipped to the horizontal conductor, the hangers are usually rigidly attached at both ends, as the duplication of horizontal wires assures uniform flexibility, regardless of the hangers.

TANGENT CONSTRUCTION

Number of Hangers per Span. Pantagraph or Bow Trolleys

Labor and Equipment for Erection. — The following description from a paper on the Denver and Interurban Ry. in the *Proc. Am. Soc. Civil Eng.*, August, 1908, p. 540, is typical of the best practice. The line is for 11,000-volt single-phase operation.

The overhead line was put up rapidly with the assistance of a steam construction train and in one day's work 26 men installed 117 poles, including digging holes and tamping. A different construction train was used for erecting the brackets. For this service a number of box freight cars were equipped with a scaffold on the tops of the cars. With a train of five cars work could be done on four or five poles simultaneously, and 150 brackets were erected per day with 18 men. For stringing the catenary a derrick car was used, arranged to carry the reels and pay the wire out over elevated rollers. The best day's run on messenger wire was 7 miles strung and tied in. This took 17 workmen and two train crews. The best day's run on stringing and splicing trolley wire was also 7 miles, with 12 workmen and one train crew. The best day's record of clipping up messenger and trolley wire was 3½ miles with 13 workmen and one train crew. A working day consisted of nine hours, with transportation from headquarters each day on the company's time, leaving about seven working hours. The ground wires and feeder wires were placed before the brackets were erected, and the wire was paid out over the end of the boom of the derrick.

Equalization of Tension in Adjacent Spans. — The calculated sag table was verified by a special dynamometer consisting of a calibrated car spring. The use of this dynamometer disclosed a point of interest in connection with the erection of long lengths of wire and cable. For an average sag of the messenger cable, which according to the sag table should result in a tension of 2300 pounds, the dynamometer showed an initial tension of 6000 pounds. This initial strain decreased to 4000 pounds before quitting, and after expansion and contraction over night came down to the figure in the sag table. This excessive initial strain occurred on a portion of the line which is full of curves and was due to the lack of equilization between spans of the 1-mile section. On tangents the initial strain was between 3500 and 4000 pounds. This is a point to be borne in mind in calculating the proper elastic limit for such wires and cables.

TYPICAL EXAMPLES OF CATENARY CONSTURCTION. — The following examples are given to illustrate in greater detail the methods employed in catenary construction.

New York, New Haven & Hartford R.R. — The overhead construction of this railroad represents the latest and most substantial work of its type in America, and operates the heaviest and fastest type of trunk-line trains. The original overhead construction consisted of a rigid double-catenary system with equilateral triangular steel-pipe frames of different lengths joining two steel messenger cables to the copper trolley wire. This, being found too rigid, was modified by the addition of a steel contact wire suspended from the copper by clips midway between hangers. Considerations of economy and the desirability of securing better lightning protection led to the construction described below, wherein the live conductors are protected by grounded cables above them.

Tangent Construction. — Steel lattice bents are spaced 300 feet apart to support the wires. They consist of girders resting on and rigidly attached to columns which, when viewed along the track, taper to a minimum width at the base, and viewed across the track have parallel sides. A cast-iron saddle bolted to the top of the girders over each track carries a ⅞-inch galvanized steel 19-wire messenger cable which runs continuously from bent to bent with a normal sag of 6.42 feet at 60° F. At points 75 feet each side of every bent these messenger cables are joined by a 3-inch 5½-pound I-beam spanning all the tracks. These I-beams are attached to the messengers by means of clamps as shown in Fig. 33. The system thus far described is grounded and serves the double purpose of a support for the catenary construction and a lightning protection for the conductors.

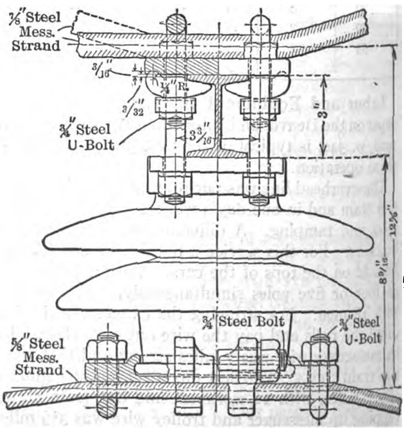

Fig. 33. N. Y., N. H. & H. Tangent Construction

Over the center of each track there is bolted to the bottom of the I-beam a porcelain insulator of the type shown in Fig. 33. These insulators occur every 150 feet along the track and serve to support a ⅝-inch steel 19-wire cable which runs continuously over the center of each track. Hangers of various lengths, such as shown in Fig. 34, depend from this steel cable at intervals of 10 feet and support a 0000 B. & S. grooved trolley wire in an approximately horizontal position. Midway between these hangers clips are attached, supporting a 0000-grooved steel contact wire, the whole construction being shown in elevation in Fig. 35. The object of placing the clips between hangers is to give flexibility to the contact wire by reducing the resistance to upward spring.

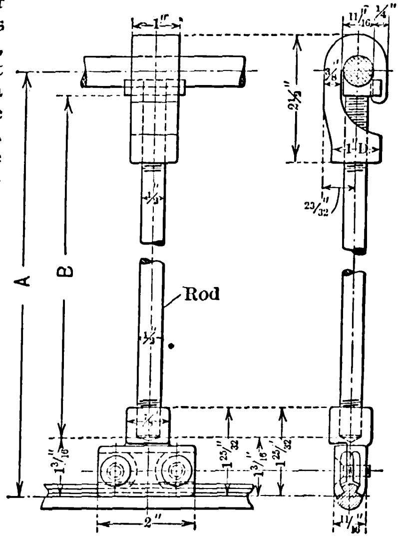

Fig. 34. N. Y., N. H. & H. Hangers

Curve Construction. — On curves up to 3 or 4 degrees, the use of pull-offs and bridle construction is avoided by a modification of the tangent construction, whereby the ⅝-inch messenger cable itself acts as a bridle and the hangers do duty as pull-offs. This is accomplished by installing the ⅝-inch messenger cable well outside of the center line of the pantograph and using slanting hangers bolted to the clips, instead of the usual vertical hangers located between clips. A plan view of this construction looks like a bridle with pull-

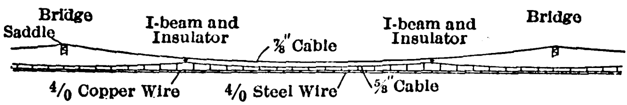

Fig. 35. N. Y., N. H. & H. Compound Catenary

offs and an elevation looks like the standard tangent construction. The inclined position of the hangers gives the requisite flexibility to the contact wire in spite of the clips being attached to the hangers. The spacing of the bents is reduced on curves to between 180 and 200 feet.

Curves greater than 3.5 degrees require pull-offs to keep the contact wire over the pantagraph shoe. These pull-offs are attached to extra clips between the hanger clips and are anchored either to a bridle construction or to poles, according to local requirements.

Yard Construction. — In yards a wire span between two poles replaces the bent used in main-line construction, the insulators being suspended from the cross-span by 5/16-inch soft-steel cable. A horizontal steady-wire insulated by strains slightly above the level of the contact wire supports the steady-hangers to which the contact wire is clipped. On curves, an additional insulated steady-wire is attached to the messenger wire at the poles. The messenger

wire is often reduced from 5/8 inch to 3/8 inch and the hangers are spaced 15 feet on tangents and 10 feet on curves. No copper trolley is used.

Insulated Sections. — The main-line conductors are divided into sections from cross-over to cross-over. Wherever conditions permit, sections are insulated by staggering the contact wires laterally and running the two wires parallel, 18 inches apart, each to a separate insulator. The ends are turned up to avoid catching the pantograph.

Turnouts. — Turnouts are made by means of steel deflectors or frames which keep the diverging wires at a fixed angle apart.

Stresses in Spans. — The stresses in the 7/8-inch cable are as follows on a tangent 300-foot span.

Condition	Temperature, ° F.	Sag, ft.	Stress, lb.
Normal	60	6.42	7,550
Normal	−10	5.71	8,550
Sleet and wind	−10	6.46	14,750

The stresses in the 5/8-inch cable are as follows on a tangent 140-foot span.

Condition	Temperature, ° F.	Stress, lb.
Normal	60	4930
Normal	−10	7100
Sleet and wind	−10	8400

The stresses in the copper wire and contact wire are negligible. Sleet is assumed to cover the wire to a depth of one-half inch and the wind is assumed to exert a pressure of 2/3 of 8 pounds per square foot.

Hangers. — The longest hangers (140 feet apart) have a length of 15 9/16 inches measured between centers of wires. The shortest hangers are 4½ inches long. For main-line construction they are made of ½-inch rods, for yards, of 3/8-inch rods. (*The above details of the N. Y., N. H. & H. R.R. published by courtesy of Mr. W. S. Murray.*)

Catenary Construction on Austrian State Railways. — The working conductor is suspended from a compound catenary. It is of hard-drawn copper, has a cross-section of 154,000 circular mils, and is supported at intervals of 10 feet by clamps loosely hung on the auxiliary catenary. The auxiliary catenary is a steel wire 0.24 inch in diameter suspended from the main catenary at intervals of about 19½ feet by hangers which are rigidly attached at both ends. The main catenary is a seven-strand steel cable having a total cross-section of 68,000 circular mils. In the tunnels where there is much moisture, bronze is substituted for steel in the catenary construction. The working conductor is prevented from swinging by gas-pipe braces insulated with two petticoat insulators in series. On curves the braces are so arranged that they are always under tension. The height of the working conductor over the top of the rail is 18 feet

in the open. An even tension is maintained on the trolley wire by inserting an automatic tension device at intervals of about 0.6 mile. The construction is carried by iron poles either of the lattice type of construction or of broad-flange I-beams. In the open where there is only one track the catenary is carried on brackets, the poles being spaced at 165 feet. In the stations where there are several tracks the overhead work is carried by a channel iron supported by two poles. All poles are grounded to the rails.

Catenary Construction in Tunnel. — In the tunnels special construction had to be used in order to carry out the compound catenary type of construction within the clearance limits imposed by the profile of the tunnel. The maximum height of the tunnel over the rails is 13.5 feet and the height of the clearance profile is 12 feet over the top of the rails. Therefore there is only 1.5 feet available for the overhead construction. The working conductor was brought within 2 inches of the clearance profile — that is, 12 feet 2 inches over the top of the rail, — and the construction was supported at intervals of about 60 feet by three-part insulators mounted in the upper part of the tunnel walls. One of the advantages of mounting insulators on the side walls was the freedom from trouble due to locomotive smoke during the period when steam locomotives were still used on the road.

Insulated Sections. — The overhead conductor is provided with a section insulator at both ends of all tunnels and at all stations so that these portions of the road can be isolated in case of trouble. Then, in order not to interfere with the operation of the road as a whole, by-pass lines are carried around the tunnels and around the stations. The switches connected to these by-pass lines are mounted on the poles and operated from the ground by rods. The section insulators themselves are carried by two brackets spaced about 33 feet apart, between which two working conductors are strung parallel to each other and about 1 foot apart. Between these points the two conductors are inclined horizontally in opposite directions, and therefore in passing along the conductor the current collector is transferred from one to the other without shock. At stations section insulators are very much simplified, and instead of overlapping the sections, as described above, the insulator is built right into the line itself. (*El. W., 1912, Vol. 59, p. 1253, with dimensions corrected.*)

SPECIFICATIONS. — (*See also article on Specifications.*) Specifications for trolley wire are given under *Wires and Cables, Bare,* and for insulators under *Insulators for Overhead Lines.*

Globe and Brooklyn Strains. — The following data should be given:

Dimensions, size of eye, etc.

All samples tested to destruction shall break in the eye.

The average ultimate tensile strength of all samples subjected to mechanical test shall not be less than a stated number of pounds, and no individual sample shall show a tensile strength of less than 85 per cent of the average tensile strength of all the samples that are tested.

The average breakdown voltage for samples which have been broken in the eye in the mechanical test shall be not less than a stated number of volts, and no individual sample shall break down at less than 90 per cent of that voltage.

Round-top Hangers. — Round-top hangers, when suspended free from draught in an inverted position by means of a bronze ear weighing 8 ounces and being 5½ inches long, the ear clamping the middle of a round rod of soft iron ¼ inch in diameter, and of at least 20 inches length between connectors, must be able, without breaking down or becoming permanently deformed by more than 1/16 inch, to sustain a weight of 200 pounds from the cap for one hour, a

current of 200 amperes being passed continually through the iron rod, the rod being cold at the start. (*Sheldon and Keiley, Vol. 22, Trans. A.I.E.E., 1903.*)

OPERATION. — The operation of overhead lines for low-speed cars presents few difficulties owing to the adaptability of the trolley pole and wheel at such speeds. With high-speed cars the case is different, as the collector vibrates rapidly and the line must be kept uniformly level, smooth and elastic throughout and all special work must be maintained in first-class condition. If the collector vibrates in resonance with the loops in the contact wire, an increase in the number of supports will usually cure the trouble.

Prevention of Formation of Sleet. — Sleet may be prevented from forming on the wires by greasing the latter with petroleum jelly and if it does form it may be easily removed by any of the numerous commercial forms of sleet cutters.

Wear of Trolley Wheel, Bow and Trolley Wire. — The wear of the trolley wires is not serious either with wheel or bow collectors. On the lines of the Indianapolis & Cincinnati Traction Co., a copper trolley wire lost less than 1 per cent in weight after it had experienced 39,000 car movements, each car taking an average of about 40 amperes by an aluminum slider.

The vertical wear of the steel contact wire on the N. Y., N. H. & H. R.R. was 0.028 inch in thirty months, which is practically 4.5 per cent per year of the half diameter of the wire (one-half taken to permit wire to be held in clips) which, even on this vertical diameter basis, indicates a life of over 20 years; but as a matter of fact it will be much more than this, for the reason that as the vertical diameter lessens the breadth of contact increases throughout, thus diminishing the rate of vertical wear. Of further interest is the fact that there is practically no corrosion of the wire, for like the traffic rails in service, the wire is covered with a film of grease deposited by the pantograph shoe (*W. S. Murray*).

Change in Length of Trolley Wire. — The change in length of copper due to changes in temperature is one of the greatest difficulties in the maintenance of overhead work. A drop of 100° F. in temperature will cause a copper bar to contract approximately 1 inch for every 100 feet of length. If it be restrained at the ends this will cause an additional stress of 2500 pounds in a No. 0000 trolley. (*See Transmission Lines.*)

European catenary lines are usually maintained at constant tension by means of weights pulling on the free ends of the trolley wire at the end of every section.

TESTING OF TROLLEY CIRCUITS. — Trolley lines have to be tested, (1) for resistance, and (2) for insulation from ground. The resistance may be measured by grounding one end of the wire to the track rails and circulating current at reduced voltage. The drop in the overhead lines may be measured using another trolley wire, a telephone wire or the earth as a potential lead. If the earth is used, the connections to ground should be sufficiently far from the track rails to be outside the zone of potential disturbance (*see Electrolysis of Underground Structures*).

REPAIRS OF TROLLEY CIRCUITS. — The repair methods of four typical railways are given below.

Philadelphia Rapid Transit Co. — The maintenance department is divided into regular maintenance crews and emergency crews and a pole gang, which are under separate foremen. The regular maintenance foreman has two crews consisting of two linemen, one helper and a driver, and the pole gang consists of the foreman and five helpers. The emergency foreman is in charge of seven emergency stations in winter and eight in summer. The crews in these stations consist of two linemen, two helpers and two drivers divided into day and night

shifts on duty 12 hours each. The eight stations care for approximately 75 miles of line each, although when necessary the crews answer calls outside of their own districts. The equipment of the stations consists of one two-horse telescopic tower wagon and four horses. In addition, three of the stations are equipped with telescopic tower cars for heavy work. (*Elect. Ry. Journal, 1908, Vol. 22, p. 856.*)

Detroit United Railway Co. — The maintenance force of this company consists of 23 men under the direction of a city line foreman reporting to the superintendent of power. Three construction tower wagons are kept on regular maintenance work, and for heavy emergency work two tower line cars are used. These cars distribute line supplies and material and are called on to aid in moving disabled cars or other heavy work. The crews of these cars consist of a motorman and two linemen.

One emergency station in the center of the city serves 186 miles of city lines. Its equipment includes two one-horse, ball-bearing, light tower wagons, a hose jumper wagon, wreck wagon and four horses. Two men are on duty night and day, and in addition the two line cars and their crews are stationed in the same building when not engaged in outside work. This emergency station answers approximately 300 calls a month for trolley-wire breakdowns. The horses are not kept harnessed, but the wagons have quick-hitch harness. (*Elec. Ry. Journ., 1908, Vol. 22, p. 858.*)

Birmingham Railway, Light & Power Co. — The maintenance force for the overhead lines consists of two foremen and 12 men, who are under the superintendent of the electric department. Only one emergency station is used for the entire system. Its equipment includes one two-horse tower wagon, one one-horse buggy on which a ladder is carried and one motor tower car for heavy repairs and emergency work on the suburban lines. This station answers as many as 350 calls a month for all kinds of emergency repairs.

Illinois Traction System. — The line is divided, for overhead maintenance purposes, into districts averaging 90 miles in length. A line foreman and three helpers are assigned to each district and are given a tower line car with a regular crew. The members of the crew act as groundmen on heavy repair work.

COST OF TROLLEY CONSTRUCTION. — The costs given in the following tables will serve as a rough guide in making preliminary estimates.

Extras for Curves. — Under ordinary conditions curves add about 10 per cent to the cost of direct-suspension construction and about 15 per cent to the cost of catenary construction.

Extras for 1200-volt Construction. — The following amounts should be added to give proper values for 1200-volt construction:

Direct suspension:	
Bracket construction	$40.00
Span construction	40.00
Catenary suspension:	
Bracket construction	$10.00
Span construction	10.00

Cost of 11,000-volt Catenary Construction. — Under favorable conditions, an 11,000-volt catenary construction, such as that of the Denver and Interurban Ry., with sufficient conductors for a half-hourly operation of two-car trains, including track bonding, costs from $3500 to $5000 per mile of single track. (*O. S. Lyford, Proc. Am. Soc. Civil Eng., August, 1908, p. 540.*)

COST PER MILE OF SPAN-WIRE TROLLEY CONSTRUCTION (600 VOLTS)

(Exclusive of Track Work and Bonding.)

For heavy catenary construction, such as used on trunk-line railways, the cost depends entirely upon the standards selected, which are inclusive of the consideration of importance of track, in turn bringing into consideration the advisability of wood- and steel-post construction, cross-catenary and bridge-span construction, single or compound catenaries, etc. The cost of overhead yard construction can vary from $1500 to $3000 a mile of single track, depending upon number of tracks spanned and type of construction selected.

COMPARATIVE COST PER MILE OF SINGLE-TRACK DIRECT SUSPENSION AND CATENARY CONSTRUCTION

Adapted from (*G. E. Review, 1910, Vol. 13, p. 516.*)

600-volt Line, Tangent Track

Item	Direct suspension		Catenary, three-point	
	Bracket	Span	Bracket	Span

[W. A. DEL MAR.]

TROLLEY SYSTEMS, UNDERGROUND.— (*See also Trolley Systems, Overhead.*) This system is little used on account of its cost, the installations at Buda-Pest, New York, Washington and London being the only notable ones. The essential feature of all these systems is the underground conductor which is reached from the car by a "Plough" extending through a continuous slot parallel to the tracks.

NEW YORK SYSTEM. — The most successful construction is the latest New York type, a brief description of which is given below.

General Description. — The street is excavated and cleared of obstructions for a width of about 5 feet 6 inches and a depth of about 3 feet and cast-iron yokes (Fig. 1) set in the excavation about 5 feet apart. The track and slot rails are supported on these yokes and the whole system made solid with concrete which fills the excavation from the foundation to near the top of the rails leaving only a tunnel under the slot free from masonry. The conductors are suspended in this tunnel, by special strain insulators, no part of the electrical system being grounded. The use of two insulated conductors avoids trouble in case of accidental grounding.

Yoke. — The yoke shown in Fig. 1 is made in three parts. The lowest piece which rests on the floor of the excavation is a 6-inch steel I-beam, 4 feet 8 inches long. Two castings 6½ inches wide are riveted to this, each one serving to support one track rail and one slot rail. Fig. 1 shows both slot rails in place but only one track rail. The track rail is carried on a timber stringer which extends from yoke to yoke along the whole line. The stringers are held to the yokes by countersunk iron plates the ends of which project beyond the stringer and have holes which accommodate bolts running through the yoke. These bolts serve the additional purpose of fastening the rails to the stringers as they also pass through clips which bear upon the foot of the rail. The rails are further secured by long bolts running to the center of the yoke. The slot rails are bolted direct to the yoke and are connected to the track rails by long bolts every 30 inches.

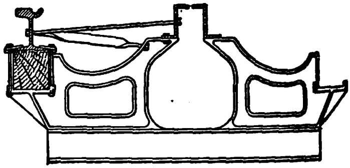

Fig. 1.

Insulator Boxes. — A pair of cast-iron boxes are laid across from the slot rails to the track rails and bolted to them every 15 feet as shown in Fig. 2. These contain the insulators which support the contact conductors. Inside each box is a pair of shelves running normal to the track; resting on these shelves and bolted to them is a cast-iron bridge which holds the insulator. The top of the box is provided with a cast-iron cover which is flush with the street surface.

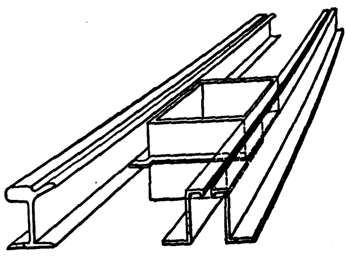

Fig. 2.

Concrete Work. — When the iron work is laid the tunnel which is to protect the conductors and do the draining is formed with collapsible sheet iron, fitting closely to the center opening of the yokes and run from yoke to yoke. The space from the bottom

of the insulator boxes to the road foundation is formed with boards. Concrete is then poured into the excavation completely filling every part but the tunnel and its offsets at the insulator boxes. The concrete is poured to within the height of a paving block of the rail tops. When the concrete is hard the sheet-iron form is collapsed and pulled along to the next section. The forms at the bottom of the insulator boxes being collapsible are drawn out through

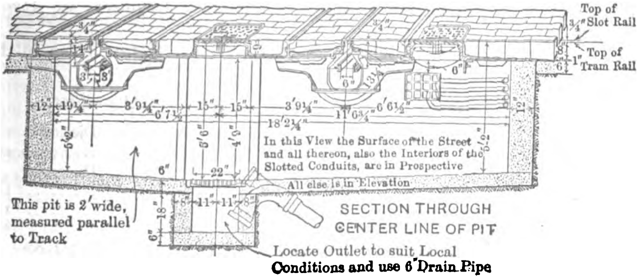

Fig. 3.

the handholes and are used again elsewhere. The depth of the completed tunnel is 18 inches from the base of the slot rails. A view of an older New York City construction is shown in Fig. 3, which is taken from an article in the *Street Railway Journal*.

THE LONDON SYSTEM has alternate long and short yokes, the long ones fulfilling the same function as the New York ones, the short ones serving merely to give additional support to the slot rails. No stringers are used, the rails resting on hard-wood blocks at the yokes only.

THE BUDA-PEST CONSTRUCTION has the slot in the track rail, thus saving considerable iron, but necessitating an excessively wide slot to accommodate the wheel flanges.

COSTS. — The type of construction in New York City cost from $60,000 to $100,000 per mile of track, exclusive of feeders, depending upon the conditions under which it was installed.

UNITS AND CONVERSION FACTORS. — In this article are given the numerical interrelations, or "conversion factors" for all the commonly employed English and metric units. For the definitions of the various quantities see *Mechanics, Principles of; Heat and Thermal Properties; Temperature; Electricity and Magnetism, Principles of; Alternating Currents; Units, Practical Electrical;* and *Photometric Quantities*. For a list of the abbreviations and symbols adopted by the American Institute of Electrical Engineers see *Abbreviations and Symbols*.

The following is a list of the tables of conversion factors given in this article:

SYSTEMS OF UNITS. — By the magnitude of any quantity is meant the *relative* magnitude of this quantity as compared with some other quantity *of the same nature;* e.g., a length of 10 inches means a length which is ten times the length of one inch. To measure a quantity, then, it is necessary either (1) to adopt first some fixed magnitude of the same nature which may be used as a standard of reference, or unit, or (2) to define the quantity in such a way that the unit of measurement may be derived from the arbitrarily selected units of the quantities involved in the definition.

Fundamental and Derived Units. — Units which are chosen arbitrarily are called "fundamental" units; those which are derived from a set of fundamental units are called "derived" units. All mechanical units can be derived from a set of three fundamental units; the three units ordinarily chosen as fundamental are those of length, mass and time. In relations involving temperature changes, an arbitrary unit of temperature is also chosen; to express electrical and magnetic quantities at least one electrical or magnetic unit is arbitrarily chosen; to express photometric quantities the unit of luminous intensity is arbitrarily chosen. These arbitrarily chosen non-mechanical units are called "auxiliary fundamental" units.

English and Metric Systems of Units. — There are two systems of mechanical units in use in English speaking countries, the English and the French, or metric, systems. The latter system is used universally by physicists in all civilized countries and also forms the basis of the electrostatic and elec-

tromagnetic systems of electric units used by engineers as well as physicists. The English system of mechanical units, however, is used almost universally by English speaking peoples, in engineering, in commerce and in the arts; it is also the basis of the system of thermal units used largely by engineers. Engineers, however, are coming to use the metric system to a greater and greater extent for all purposes.

In both the English and the metric systems length, mass and time are chosen as the fundamental quantities. In the English system the fundamental units for these three quantities are respectively the foot, the pound (avoirdupois) and the second; this system is therefore also called the foot-pound-second system. In the metric system the corresponding units are the centimeter, gram and the second; this system is therefore also called the centimeter-gram-second, or c.g.s., system. The magnitudes of these fundamental units have been fixed arbitrarily by law; see below.

Absolute and Gravitational Units. — Two different units of force (and units derived therefrom) are used in both systems, viz.: (1) the unit of force is defined as that force which will give unit acceleration to unit mass, and (2) the unit of force is defined as that force which will give to unit mass an acceleration equal to the acceleration of a freely falling body under the influence of "gravity" or the pull of the earth alone (*see Mechanics, Principles of*). The first unit is called the "absolute" unit of force and the second the "gravitational" unit of force, and derived units based on these two units are called absolute and gravitational units respectively. The gravitational units are not definite unless the latitude and elevation of the point at which the acceleration due to gravity, usually represented by the symbol "g," is specified. By international agreement (*Troisème Conf. Gen. des Poids et Mes., 1901, p. 66*) the value $g_0 = 980.665$ cm. per sec. per sec. (= 32.1739 feet per sec. per sec.) has been chosen as the standard value for the acceleration due to gravity; this value of g may be called the "gravitational acceleration constant." The value 980.665 was chosen to represent the value of g at 45° latitude and sea level, but later measurements give a slightly different value of g at this latitude and elevation; the value 980.665, however, is retained as the *standard* value of g_0.

The gravitational unit of force in the English system is called the pound and in the metric system the gram, the same names being used for the unit of force as for the unit of mass. This arises from the fact that unit mass has a force exerted upon it by the earth, i.e., has a *weight*, numerically equal to its mass, when the force is expressed in terms of this gravitational unit. (This is exactly true only at the latitude and elevation for which $g = g_0$, but the variation with both latitude and elevation is usually negligible in engineering work.*) The absolute unit of force in the English system is called the poundal, but is practically never used; the absolute unit of force in the metric system is called the dyne, and is the unit of force commonly used by scientists. In engineering work the common units of force are the gravitational units, pound or gram, and their multiples and submultiples.

The relation between the absolute and gravitational units of force are:

1 pound = 32.1739 poundals,
1 gram = 980.665 dynes.

Weight and Mass. — The word weight is used in two different senses, viz.: (1) to mean the force with which the earth attracts a piece of matter,

* The force acting on a mass of 1 pound at sea level at the equator is 0.997363 pound, and at sea level at either pole of the earth is 1.002651 pound. An increase in elevation of 10,000 feet diminishes the force acting on a mass of 1 pound by only 0.00096. See Landolt, Börnstein and Roth, *Physikalish-Chemische Tabellen.*

and (2) to designate a given mass or quantity of matter; in other words, weight is used to designate both force and mass. As commonly employed the term almost invariably has its second meaning; that is, by a "weight of 10 pounds" is meant a piece of matter which has a mass of 10 pounds. A weight (2nd sense) of 10 pounds has a weight (1st sense) of 10 pounds at 45 degrees latitude and sea level (practically), but at any other latitude and elevation it has a weight (1st sense) slightly different from 10 pounds, and on the sun, for example, would have a weight (1st sense) many times 10 pounds.

In this connection it should be noted that a beam-balance when used in the ordinary way to compare two pieces of matter measures weight in the second sense (i.e., it would "read" the same whether the measurement were made on the earth or on the sun), that is, a beam-balance as ordinarily used compares masses and not forces. A beam-balance, however, is frequently used in testing (e.g., in connection with a Prony brake, see ***Index***) to compare a force produced by a machine with the pull on a standard mass (*or* "*weight*") due to gravity. If great precision is desired the reading of the balance should then be corrected for the value of "*g*" at the place of observation, but in ordinary measurements the inaccuracy of the balance is likely to be much greater than this small correction factor. For values of "*g*" at various places see reference in footnote, bottom of preceding page.

STANDARDS OF THE FUNDAMENTAL UNITS. — The physical standards upon which the c.g.s. system of units is based, and the legalized standards of the foot and pound used in Great Britain and the United States are described below.

Standard of Length. — The standard meter (100 centimeters) is the distance between two lines on a platinum-iridium bar carefully preserved at the Bureau of Weights and Measures, at Sevres, France, when the bar is kept at a uniform temperature of zero degrees centigrade throughout. In the United States the yard (3 feet) was defined by Act of Congress, July 28, 1866, as

$$\mathbf{1\ U.S.\ yard} = \frac{3600}{3937}\ \mathbf{meter},$$

and similarly the British imperial yard is defined by law as

$$1 \text{ British imperial yard} = \frac{3600}{3937.079} \text{ meter.}$$

For engineering purposes the U. S. and British yards may be considered as identical.

Standard of Mass and Force. — The standard kilogram (1000 grams) as a unit of mass is a cylinder of platinum preserved at the Bureau of Weights and Measures, at Sevres, France. The U. S. pound avoirdupois is defined by law (*Act of Congress, 1866*) as $\frac{1}{2.2046}$ kilogram, but in 1893, the Superintendent of Weights and Measures, with the approval of the Secretary of the Treasury, declared* the pound to be

$$\mathbf{1\ U.\ S.\ pound} = \frac{1}{2.204622}\ \mathbf{kilogram.}$$

The British imperial pound has the same value.

The same relations between pound and kilogram hold whether these units be taken as units of mass or as units of force, the unit of force being defined in

* Bull. Bureau Standards, 1904, Vol. 1, p. 380.

both cases as the pull of the earth on unit mass at 45 degrees latitude and sea level.

Standard of Time.—The standard second universally adopted is the $\frac{1}{86,400}$ th part of a mean solar day. The solar day is the interval of time between two successive transits of the sun across a meridian of the earth at the point of observation; this interval varies in length at different times during the year, but the average length of the interval for one year is constant as far as can be determined by any known methods of observation.

STANDARDS OF THE AUXILIARY FUNDAMENTAL UNITS.— The standards of temperature, dielectric coefficient, magnetic permeability and luminous intensity ordinarily used are defined below.

Standard of Temperature. — Two units of temperature, or temperature scales, are commonly employed, viz., the centigrade and the Fahrenheit units. The relation between these two units results solely from the manner in which they are defined.

$$1 \text{ degree centigrade} = \frac{9}{5} \text{ degrees Fahrenheit.}$$

Due to the difference in the zeros of the two scales, a temperature of t_f degrees Fahrenheit corresponds to a temperature of

$$t_c = \frac{5}{9}(t_f - 32) \text{ degrees centigrade,}$$

and vice versa,

$$t_f = \frac{9}{5} t_c + 32 \text{ degrees Fahrenheit.}$$

Standards of the Auxiliary Fundamental Electrical Units. — Three systems of electrical and magnetic units are in use, viz., (1) the c.g.s. electrostatic system, (2) the c.g.s. electromagnetic system, and (3) the practical system. In the c.g.s. electrostatic system the dielectric coefficient k of air at 0° C. and 760 mm. mercury pressure is arbitrarily chosen as unity. In the c.g.s. electromagnetic system the magnetic permeability of air under the same standard conditions is arbitrarily chosen as unity. In the practical system a concrete standard of the unit of resistance (called the ohm) is arbitrarily chosen (*see Units, Practical Electrical*); this unit resistance was originally designed to be equal to 10^9 times the unit of resistance in the c.g.s. electromagnetic system, and within the limits of ordinary experimental error this relation may still be considered exact.

Use of the Prefixes "Stat" and "Ab."— To designate the electrical and electromagnetic units in the electrostatic and electromagnetic systems of units respectively the prefixes "stat" and "ab" may be used with the name of the corresponding practical unit. For example, the c.g.s. electrostatic unit of quantity may be called the statcoulomb and the c.g.s. electromagnetic unit of quantity may be called the abcoulomb. For the names and definitions of the various electrical and magnetic units see the article on *Electricity and Magnetism, Principles of*.

Standards of Luminous Intensity. — Two standards are in use, the international candle and the hefner, the latter being used chiefly in Germany. See article on *Photometric Quantities* for the specifications for these units.

EXPERIMENTALLY DETERMINED CONVERSION FACTORS.— By conversion factor is meant the numerical factor which gives the magnitude of one unit for any given quantity in terms of any other unit for the same quantity.

For example, in the expression 1 yd. = 3600/3937 meter, the factor 3600/3937 is the conversion factor between the yard and the meter.

In the case of two units for the same quantity based on two different sets of arbitrarily chosen units which are defined independently, the conversion factor can be obtained only by experiment. The more important experimentally determined conversion factors are given in the paragraphs immediately following.

Mercury- and Water-column Pressure. — To convert pressure per unit area into height of mercury column the density of mercury must be known. Thiesen and Scheel (*Zeitsch. f. Instrk. de., 1898, Vol. 18, p. 138*) give the density of mercury at 0° C. as 13.59545 grams per (cm.)^3. Using the standard value of the gravitational acceleration constant, $g_0 = 980.665$, the relation between the dyne per sq. cm. and 1 cm. of mercury column at 0° C. is then

1 cm. mercury column at 0° C. = 13332.6 dynes per sq. cm.

Taking the density of water as 1 gram per (cm.)^3 at 4° C.,

1 cm. water column at 4° C. = 980.665 dynes per sq. cm.

Mechanical Equivalent of Heat. — Very useful units of energy are those based upon the mass of a standard substance and temperature, viz., the heat (which is energy) required to raise the temperature of a specified mass of water a specified number of degrees; see *Heat and Thermal Properties*. The experimentally determined relation between the mean small calorie (i.e., the one-hundreth part of the heat required to raise the temperature of 1 gram of water from 0° C. to 100 C. at 760 mm. mercury pressure) and the erg is

1 mean small calorie = 4.1834×10^7 ergs.

See Marks and Davis, *Steam Tables and Diagrams*, N. Y., 1912. From this relation and the relations (fixed by definition) given above between the yard and the meter, the pound and the kilogram, the value of the gravitational acceleration constant g_0, and the two temperature scales, Marks and Davis, deduce the relation

1 British thermal unit = 777.52 foot-pounds.

The British thermal unit as here used is defined as the $\frac{1}{180}$ th part of the heat required to raise the temperature of 1 pound of water from 32° F. to 212° F. at 760 mm. mercury pressure. See also *Heat and Thermal Properties*.

The experimentally determined conversion factor between the energy unit based on the units of temperature and mass, and the energy unit based on the units of length, mass and time, i.e., the unit of mechanical work, is called the "mechanical equivalent of heat."

Relations between the Three Systems of Electrical Units. — The fundamental relation, experimentally determined, between the c.g.s. electrostatic and the c.g.s. electromagnetic system is that

1 abfarad = 9×10^{20} statfarads,

which as a consequence of the definitions of the various terms is equivalent to

1 abcoulomb = 3×10^{10} statcoulombs, the erg being the unit of energy in both systems.

The fundamental relations between the c.g.s. electromagnetic system and the practical system are

1 abcoulomb = 10 coulombs,

1 erg = 10^{-7} watt-seconds, or joules,

the erg being the unit of energy in the c.g.s. electromagnetic system and the watt-second or joule the unit of energy in the practical system.

Relation between the International Candle and the Hefner. — The experimentally determined relation is

$$1 \text{ hefner} = 0.9 \text{ international candle.}$$

MULTIPLES AND SUBMULTIPLES OF UNITS. — Multiples and submultiples of the metric units are designated by the following prefixes; the relations are *definitions* and are therefore absolutely exact.

$$\text{micro} = \frac{1}{1{,}000{,}000} \quad \text{or} \quad 10^{-6}$$

$$\text{milli} = \frac{1}{1{,}000} \quad \text{or} \quad 10^{-3}$$

$$\text{centi} = \frac{1}{100} \quad \text{or} \quad 10^{-2}$$

$$\text{deci} = \frac{1}{10} \quad \text{or} \quad 10^{-1}$$

$$\text{deka} = 10 \quad \text{or} \quad 10$$

$$\text{hecto} = 100 \quad \text{or} \quad 10^{2}$$

$$\text{kilo} = 1{,}000 \quad \text{or} \quad 10^{3}$$

$$\text{myria} = 10{,}000 \quad \text{or} \quad 10^{4}$$

$$\text{mega} = 1{,}000{,}000 \quad \text{or} \quad 10^{6}$$

The multiples and submultiples of the English units are given in bold-face type in the tables below.

CALCULATION OF CONVERSION FACTORS. — The conversion factors noted above, which are either definitions or results of experiment, form the basis for the calculation of the conversion factors for the various derived units. The method of procedure is first to express one of the pair of units, say *A*, in terms of its component units (length, mass, time, temperature, capacity or resistance, and luminous intensity), then express the magnitude of each of these units in terms of the corresponding component units of *B*; the value of the resultant numerical factor is the conversion factor. For example, let it be required to find the conversion factor between pressure in pounds per square foot and pressure in dynes per square centimeter.

$$1 \text{ lb. per sq. ft.} = \frac{(1 \text{ lb. force})}{(1 \text{ ft.})^2}.$$

$$1 \text{ lb. force} = \frac{1}{2.204622} \times (1 \text{ kilogram force}).$$

$$1 \text{ kilogram force} = 1000 \times (1 \text{ gram force}).$$

$$1 \text{ gram force} = 980.665 \times (1 \text{ dyne}).$$

Therefore

$$1 \text{ lb. force} = \frac{1000 \times 980.665}{2.204622} \times (1 \text{ dyne}).$$

Also

$$1 \text{ ft.} = \frac{1}{3} \times (1 \text{ yd}).$$

$$1 \text{ yd.} = \frac{3600}{3937} \times (1 \text{ meter}).$$

$$1 \text{ meter} = 100 \times (1 \text{ cm.}).$$

Therefore

$$1 \text{ ft.} = \frac{1}{3}\left(\frac{3600}{3937}\right) \times (100) \times (1 \text{ cm.}).$$

Whence

$$\frac{1 \text{ lb. force}}{(1 \text{ ft.})^2} = \frac{1000 \times 980.665 \times (3 \times 3937)^2}{2.204622 \times (3600 \times 100)^2} \times \frac{(1 \text{ dyne})}{(1 \text{ cm.})^2}$$

$$= 478.799 \times \frac{(1 \text{ dyne})}{(1 \text{ cm.})^2}.$$

But $\dfrac{(1 \text{ dyne})}{(1 \text{ cm.})^2} = 1$ dyne per sq. cm.

Therefore

1 pound per sq. ft. = 478.799 dynes per sq. cm.

DIMENSIONAL FORMULAS. — Instead of writing the expression for a derived unit in words, it is frequently convenient to express it in algebraic symbols, using a specific symbol for each of the fundamental or auxiliary fundamental units. For example, let L stand for a length of 1 centimeter, M for a mass of 1 gram, and T for a time interval of 1 second; then the unit of force in the c.g.s. absolute system (the dyne) may be written

$$F = MLT^{-2},$$

which is the same as 1 dyne = (1 gram) $\times \dfrac{(1 \text{ cm.})}{(1 \text{ sec.})^2}$.

A formula, such as $F = MLT^{-2}$, where each letter represents the magnitude of a *single* unit of the quantity for which it stands, is called a "dimensional formula." A pure number, or a quantity which is the ratio of two units of the same dimensions, such as an angle, has zero dimensions and does not appear in a dimensional formula.

Dimensional formulas are useful for two purposes, viz., (1) as a systematic method for calculating conversion factors and (2) as a check of algebraic formulas expressing various relations. Unless one has a large number of conversion factors to calculate it is probably simpler to use the direct method given in the preceding section. Certain quantities, for example, work and torque, may have the same dimensions although they are physically entirely different. Although such quantities are physically different their conversion factors are identical. The second use of dimensional formulas is based on the fact that every term in any set of terms connected either by equal signs, plus signs or minus signs, must have the same dimensions.

For a complete list of the dimensional formulas for the various mechanical, electrical, thermal, and photometric quantities see Hering, C., *Conversion Tables*, N. Y., 1904. In the tables below are given, in the parentheses after the titles, the dimensional formulas of the mechanical quantities in terms of length, mass and time, designated by L, M and T respectively. For the electrical and magnetic quantities the dimensions are expressed in terms of electric potential difference V, quantity of electricity Q and time T. In the *c.g.s. electromagnetic system* of units Q may be expressed in terms of L, M, and T by the formula

$$Q = L^{\frac{1}{2}}M^{\frac{1}{2}}\mu^{-\frac{1}{2}};$$

in the *c.g.s. electrostatic system* by the formula

$$Q = L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-1}k^{\frac{1}{2}}.$$

In both systems $VQ = L^2MT^{-2}$ = energy.

TABLES OF CONVERSION FACTORS.* — The following tables give the most commonly required conversion factors for mechanical, electrical and magnetic quantities. See *Heat and Thermal Properties* for special heat units (other than energy) and *Photometric Quantities* for the special photometric units.

LENGTH (L)

cm. = *centimeter.* *m.* = *meter.*
ft. = *foot.* *mi.* = *mile.*
in. = *inch.* *mm.* = *millimeter.*
km. = *kilometer.* *yd.* = *yard.*

1 centimeter	1 foot	1 inch	1 kilometer	1 knot
0.3937 in.	30.48 cm.	2.540 cm.	10^5 cm.	6080 ft.
0.01 m.	12 in.	0.02540 m.	3281 ft.	1.853 km.
393.7 mil	0.3048 m.	10^3 mil	1000 m.	1853 m.
10 mm.	304.8 mm.	25.40 mm.	0.6214 mi.	1.152 mi.
....	0.3333 yd.	....	1094 yd.	2027 yd.

1 meter	1 mil	1 mile	1 millimeter	1 yard
100 cm.	0.002540 cm.	1.609×10^5 cm.	0.1 cm.	91.44 cm.
3.281 ft.	0.001 in.	5280 ft.	0.03937 in.	3 ft.
39.37 in.	0.02540 mm.	1.609 km.	0.001 meter	36 in.
0.001 km.	....	1609 m.	39.37 mil.	0.9144 meter
1000 mm.	....	1760 yd.	....	....
1.094 yd.	....	....	....	....

* **Example.** — 7 yards equals how many meters? *Answer*, 1 yard = 0.9144 meters, therefore 7 yards = $7 \times 0.9144 = 6.4008$ meters.

AREA (L^2)

C.M. = *circular mil.*

[H. PENDER and R. G. HUDSON.]

UNITS, PRACTICAL ELECTRIC. — (*See also Electricity and Magnetism, Principles of; Units and Conversion Factors.*) Following the recommendation of the Chicago International Electrical Congress of 1893, the following Act was passed by Congress. (Act approved July 12, 1894.) *Be it enacted, etc.* That from and after the passage of this act the legal units of electrical measure in the United States shall be as follows:

First. The unit of resistance shall be what is known as the international ohm, which is substantially equal to one thousand million units of resistance of the centimeter-gram-second system of electromagnetic units, and is represented by the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice fourteen and four thousand five hundred and twenty-one ten-thousandths (14.4521) grams in mass, of a constant cross-sectional area, and of the length of one hundred and six and three-tenths (106.3) centimeters.

Second. The unit of current shall be what is known as the international ampere, which is one-tenth of the unit of current of the centimeter-gram-second system of electromagnetic units, and is the practical equivalent of the unvarying current, which, when passed through a solution of nitrate of silver in water in accordance with standard specifications, deposits silver at the rate of one thousand one hundred and eighteen millionths (0.001118) of a gram per second.

Third. The unit of electromotive force shall be what is known as the international volt, which is the electromotive force that, steadily applied to a conductor whose resistance is one international ohm, will produce a current of an international ampere, and is practically equivalent to $\frac{1000^*}{1434}$ of the electromotive force between the poles or electrodes of the voltaic cell known as Clark's cell, at a temperature of fifteen degrees centigrade (15° C.), and prepared in the manner described in the standard specifications.

Fourth. The unit of quantity shall be what is known as the international coulomb, which is the quantity of electricity transferred by a current of one international ampere in one second.

Fifth. The unit of capacity shall be what is known as the international farad, which is the capacity of a condenser charged to a potential of one international volt by one international coulomb of electricity.

Sixth. The unit of work shall be the joule, which is equal to ten million units of work in the centimeter-gram-second system, and which is practically equivalent to the energy expended in one second by an international ampere in an international ohm.

Seventh. The unit of power shall be the watt, which is equal to ten million units of power in the centimeter-gram-second system, and which is practically equivalent to the work done at the rate of one joule per second.

Eighth. The unit of induction shall be the henry, which is the induction in a circuit when the electromotive force induced in this circuit is one international volt while the inducing current varies at the rate of one ampere per second.

SECTION 2. That it shall be the duty of the National Academy of Sciences to prescribe and publish, as soon as possible after the passage of this act, such specifications of detail as shall be necessary for the practical application of the definitions of the ampere and volt hereinbefore given, and such specifications shall be the standard specifications herein mentioned.

NOTES ON THE ABOVE DEFINITIONS. — The specifications mentioned above were prepared by a committee, and their report, based on the best

* Later experiments give an e.m.f. of 1.4328 volts at 15° C.

work that had been done up to that time, was accepted and adopted by the National Academy of Sciences on February 9, 1895.

Attention is called to the wording of the definitions of the three fundamental quantities:

1. The international ohm is based upon, but *not stated to be equal* to, 10^9 c.g.s. units of resistance; it is, however, *definitely defined* in terms of a column of mercury.

2. The international ampere *is* one-tenth of the c.g.s. unit of current, and is stated to be represented *sufficiently well for practical purposes* by the current which deposits a definite mass of silver per second under specified conditions.

3. The international volt is the e.m.f. which will cause an international ampere to flow through an international ohm, and is stated to be represented *sufficiently well for practical purposes* by a definite fractional part of the e.m.f. of the Clark cell.

Subsequent investigation has shown that the figures for the silver voltameter and the Clark cell are not equivalent. The e.m.f. of the Clark cell is really 1.4328 international volts at 15°.

PRACTICAL STANDARDS. — The Act of July 12, 1894, is still in force but advantage has been taken of the manner of stating how the international volt shall be practically realized to use as a standard of e.m.f. the Weston normal cell instead of the Clark cell (*see Cells, Standard*).

Standard resistance coils (*see Resistors, Standard*) are used as secondary standards of resistance. These are usually accurately adjusted by the makers. When great accuracy is required these standard resistances should be sent to the Bureau of Standards for calibration. Much more accurate results can be obtained in an ordinary laboratory by using properly calibrated secondary standards than by attempting to construct primary standards in accordance with the definitions in the above Act.

The use of a voltameter for the calibration of current-measuring instruments is also now seldom employed. A more accurate method for ordinary laboratory work is to determine, by means of a properly calibrated potentiometer (q.v.), the voltage drop produced by the current through a standard resistance.

Stand., 1908, Vol. 5, p. 243; *Announcement of Change in Value of the International Volt*, Circ. No. 29, Bureau of Standards.

[H. PENDER.]

UNLOADERS, COAL AND ORE. — (*See also Cranes; Motors, Industrial Applications of; Power Stations.*) Coal and ore unloaders may be divided into two distinct classes, namely, the stiff-leg type and the bridge type. Both are adapted to electric drive and each possesses certain advantages under the conditions for which it is designed. Unloaders range in capacity from three to fifteen tons per bucket load. The capacity in tons per hour varies within wide limits, but records have been established where under normal operating conditions four 15-ton equipments unloaded 10,000 tons in five hours. The power required naturally also varies under different conditions, but an average of from 0.4 to 0.5 kilowatt hour per ton is not uncommon.

STIFF-LEG UNLOADERS (Fig. 1) are mainly used at receiving docks for unloading ore from the boat to railway cars or to a large concrete trough from which it is in turn transferred to the storage yards by means of ore bridges. The machine, as seen from Fig. 1, consists essentially of a massive pantograph, the short leg of which forms an integral part of the carriage *C*. This leg is rigidly vertical, hence the stiff leg *L* which carries the bucket *B* must always be vertical. The weight of the moving parts of the link motion is nearly counterbalanced at *W* by the main hoist, rotation and bucket motors and their respective drums. The motor house on the carriage *C* contains the trolley motor and the magnetic control panels for all the above motors. The carriage is mounted on trucks and moves back and forth on the girder runway *G*. The girder structure supports a hopper with rotating gates which receives the ore from the bucket *B* and distributes it slowly to the weighing larry which in turn deposits it in the ore car underneath or in the concrete trough *I*. Cables from the main hoist drum at *W* are attached to the rear of the carriage. The operator rides in the bucket leg and has absolute control of lowering, opening, closing, bucket rotation, hoisting and trolleying movements. The entire girder structure is mounted on trucks and can be run along the dock at will by means of the bridge movement motor. Magnetic control is employed throughout and all motors except leg-rotation and bridge-movement motors are arranged for dynamic braking.

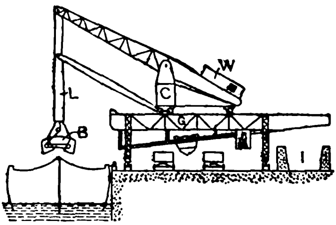

Fig. 1. Stiff-leg Unloader

Cycles of Motor Movements. — The service of the main hoist and opening and closing motor is intermittent with continuous repetition of cycle often at the rate of one round trip per minute for several consecutive hours. The leg rotation motor is used chiefly in cleaning up the bottom of the boat between hatches and involves rapid and frequent reversals at irregular intervals. The trolley-motor cycle includes acceleration, free running, retardation, reversal and repeat with every bucket load hoisted. The ore-gate motor operates intermittently whenever ore is distributed to the weighing larry. The larry travel and hopper-gate motors both operate on a continuously repeated cycle of short duration. The bridge-movement motor is used only at irregular intervals for locating the bucket over the hatches.

Motor Equipment. — The following table shows the motor equipment of a modern unloader of the stiff-leg type. The main-hoist motor has a continuous rating, but all the others are rated on an intermittent basis.

MOTOR EQUIPMENT, 15-TON STIFF-LEG UNLOADER

No. of motors	H.P.	R.p.m.	Volts, d-c.	Application	Type of motor
1	135	350	230	Main hoist	Compound wound
1	75	500	230	Trolley	Compound wound
1	75	500	230	Bucket { Opening Closing	Compound wound
1	100	450	230	Ore gates	Compound wound
1	100	450	230	Larry	Compound wound
1	100	450	230	Bridge movement	Compound wound
1	20	750	230	Leg rotation	Series wound
1	30	750	230	Larry hopper	Series wound

BRIDGE-TYPE UNLOADERS (Figs. 2 and 3) can be divided into two general classes, viz., the "man-trolley" and the "rope-trolley." In the former all hoisting and conveying motors together with a cab containing the control equipment and operator are mounted on a carriage which runs the length of the bridge, as shown in Fig. 2. In the rope-trolley unloader the motors are located in a stationary motor house and power is transmitted to the hoisting drum and carriage by means of cables, as shown in Fig. 3. The operator is also located in a stationary cab as seen.

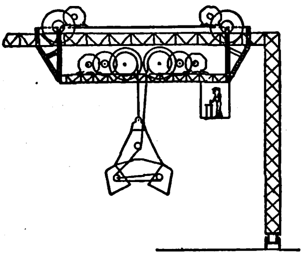

Fig. 2. "Man-trolley" Bridge Unloader

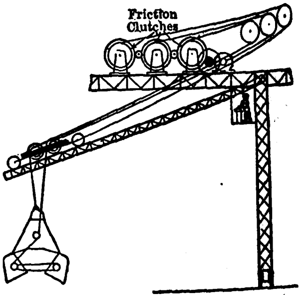

Fig. 3. "Rope-trolley" Bridge Unloader

MOTOR EQUIPMENT, 625-FOOT "MAN-TROLLEY" BRIDGE UNLOADER

1	25	430	250	Travel	Series wound
1	11	...	250	Bucket twist	Series wound
1	15	...	250	Car-loading drums	Shunt wound

TYPE OF MOTOR.—The selection of the most suitable type of motor for coal and ore bridge work must be determined for each specific installation by local considerations. In general the requirements are not quite as severe as those commonly included under the term "steel mill service," and standard industrial motors in a few instances have been used for high-speed bridges with entire success. As a rule, however, especially for ore bridges, the mill-type motor is recommended, since even under the best conditions the short cycle, rapid and frequent acceleration, severe vibration, dirt and moisture, all demand the most rugged construction.

The question of alternating- or direct-current motors is usually one of comparative first costs, costs of maintenance and operation. Where adjustable speeds under variable load are required the induction motor with its constant-speed characteristics is somewhat at a disadvantage if compared with the direct-current motor equipped with interpoles and best available control. For dynamic braking the direct-current motor also offers fewer complications in the control. Furthermore, for the rack movement or trolley travel the acceleration losses are less for the series direct-current motor. On the other hand, the efficiency of transformation and distribution of power is considerably higher for alternating- than for direct-current systems so that the apparent gain due to the characteristic of the series motor is more than offset by the simplicity and ruggedness of the induction motor, the elimination of motor-generator sets, equalizer sets and in some cases even of static transformers.

[D. B. Rushmore, assisted by E. A. Lof.]

VALVES. — (*See also Boilers; Gas Engines; Pipes; Power Stations; Steam Engines; Steam Turbines.*) The following types of valves are used to control the flow of fluids in pipes.

Gate Valve. — The opening in this valve is perpendicular to the axis of the pipe, and is closed by a disk which moves across the opening. A gate valve offers but little resistance to the flow of the fluid, since when fully opened it provides a straight passage the full diameter of the pipe (*see Pipe and Piping*).

Globe Valve. — In this valve the opening is in a partition parallel to and passing through the axis of the pipe. The opening is closed by a mushroom-shaped disk which is screwed down against the partition. The name "globe" valve arises from the globular form of the casing. The passage through a globe valve has the general shape of the letter S, and consequently offers considerable resistance to the flow (*see Pipe and Piping*). It is simpler in construction and cheaper than a gate valve, and the contact surfaces are more easily ground.

Angle Valve. — This valve has the inlet and outlet at right angles to each other; it may therefore be installed in place of an elbow. The opening is at right angles to the inlet. The closing mechanism may be either of the gate or of the globe type.

Cocks. — This type of valve consists of a conical plug with a hole through it perpendicular to its axis, mounted in a suitable casing. The valve is opened by turning the plug so that the hole is in line with the pipe and is closed by giving the plug a quarter turn. Cocks are frequently used on blow-off piping.

Stop Valves. — A stop valve is any valve that is controlled by hand or other external means, and used to stop the flow of fluid in a pipe.

Check Valves. — A check valve is any valve which opens automatically when the pressure in the normal direction reaches a predetermined value, but remains closed when the pressure is less than this amount or is in the opposite direction. Ordinary forms of check valves resemble a globe valve without a valve spindle. The closing device may be a disk, ball or cup. When the disk is arranged to swing about an axis like a hinge the valve is called a "swing check," or "flap valve," or "butterfly valve." When the disk or other device is lifted vertically, the valve is called a "lift-check valve." A check valve placed at the base of the suction pipe of a pump is called a "foot valve."

Safety Valves. — Lift check valves provided either with a helical spring or with a ball and lever mechanism to hold the valve closed under normal pressure are used as safety valves; the former type is called a pop safety valve, the latter a lever safety valve. The pop safety valve has practically supplanted the lever type, since it closes more promptly and is less liable to leak.

Relief Valves. — Check valves used to relieve excessive back pressure in atmospheric exhaust pipes are called "back-pressure valves," and when used in the piping to condensers to relieve excessive pressure are called "atmospheric relief valves."

Reducing Valves are used when it is desired to obtain steam at a pressure less than that of the boiler. In this type of valve the opening is relatively small, and the steam in expanding through this small opening has its pressure reduced. The proper size of opening for various rates of flow is maintained automatically by balancing the force produced on the closing mechanism by the pressure on the low-pressure side of the valve against the force produced on this mechanism by a helical spring. The size of the opening then adjusts itself automatically to maintain this balance irrespective of the rate of flow.

ELECTRICAL OPERATION OF VALVES.* — (*See also Motors, Industrial Applications of.*) The advantages of electrical motor operation for large valves is emphasized not only by the fact that such valves must be closed in a very short time, which would be impossible with hand control, but also by the fact that remote control is very often essential, as, for example, in hydroelectric power developments where it becomes desirable to control the gate valves from the control switchboard. The service of valve motors is exceedingly intermittent and may vary from comparatively short intervals, such as once every hour, to weeks or even months. Due to the intermittent nature of the service, efficiency or power factor need not be considered in this kind of motor application, the main consideration being the most reliable system of operation.

Size of Motor. — The proper size of a motor for driving a valve will vary with the duty and conditions under which the valve operates. A small valve may only require a one-horse-power motor, whereas very large valves, such as the Stoney-Gate valves at Panama, require 40-horse-power motors. The required motor capacity also depends to a large extent on the pressure on the valve. When opening the valve, the torque is a maximum shortly after the time of unseating, that is, after the wedges have been released and the actual motion begins. The torque then drops some until the valve has opened about one-fourth, after which it takes comparatively little power to complete the opening. When closing the valve, friction only needs to be overcome in starting as there is no pressure on the valve until it has begun to close. After the valve is about three-fourths closed the pressure causes the torque to increase rapidly. At the end of the closing cycle the torque does not, however, reach the value it did during the period of starting.

Type of Motor. — Either direct- or alternating-current motors may be used. With the former the series- or compound-wound type is generally used as it gives a high starting torque. With the latter the squirrel-cage induction motor is most widely used for small- and medium-size valves, principally on account of its simplicity. To overcome the sticking when opening, the drive is sometimes provided with a "lost motion" so as to give a hammer blow. For alternating-current motors this is furthermore of value in that it permits the motor to speed up some and gain in torque before the load comes on.

Control Equipment. — Where the size of the motor permits, the simplest method of control is to throw the motor directly on the line without the use of starting resistances. The automatic overload circuit breaker which should afford protection under normal operating conditions, must be prevented from tripping during the rush of starting current. This is readily accomplished either by short-circuiting the overload coil of the circuit breaker or by opening the connections to the coil. The former is the preferable method as this will leave some overload protection even though the coil is short-circuited. A push button is generally provided for this purpose.

Limit switches which will open the circuit when the gate has reached its limit of travel should always be provided. As a further precaution against over-travel or too high closing torque the motors should preferably be geared to the valve stems through efficient and reliable friction clutches.

When the motors are too large to be thrown directly on the line, starting resistances must be provided. With direct-current series motors a permanent resistance and a running resistance are often provided. The permanent resistance remains fixed in the circuit and should be so dimensioned as to give the maximum torque required. The running resistance is short-circuited at starting until the motor current drops to any desired value, at which time a current limit relay opens the shunt circuit of the contactor used for short-circuiting

* By D. B. Rushmore.

the resistance. This running resistance should be such as to prevent excessive speed at light load and to limit the torque should the valve seat itself before the motor is disconnected. The same general scheme may be used with alternating-current motors, but with these there is no danger of exceeding the synchronous speed.

Devices for Indicating Valve Positions. — When it is desired to indicate on the switchboard the position of the gate throughout its range of travel, this can readily be done by placing a number of sliding contacts on the inside of the limit-switch housing. These contacts are then connected with a row of incandescent lamps installed on the switchboard, and as the limit switch travels along, the lamps on the board will light successively.

Another system, much more comprehensive, is used in connection with the valve motors at the Panama Canal. In connection with each limit switch there is installed a "synchronizing transmitting device." This consists merely of a small generator which is mechanically connected to and revolves with the limit switch. It is electrically connected to a small motor which is mounted on the control switchboard and there mechanically connected to some sort of indicating device such as a pointer. When the generator at the valve revolves, the motor on the board will follow in synchronism thus indicating the exact position of the valve.

[WM. KENT.]

VECTORS. — (*See also Complex Quantities.*) Any quantity which requires for its complete specification a magnitude and a direction is called a vector quantity. Such a quantity may be represented graphically by a line having a length equal to the magnitude of the quantity and a direction parallel to the direction of the quantity. Such a line is called a vector. Its direction is, in general, specified by the angles which it makes with three arbitrarily chosen lines or axes of reference. Vectors which lie in the same or in parallel planes are called co-planar vectors; the direction of a vector in the plane in which it lies (or parallel planes) may be specified by the angle which it makes with a single line of reference in this plane.

Quantities which are completely specified by magnitude and "sense" (i.e., whether positive or negative) are called scalar quantities. Forces, velocities, displacements, etc., are vector quantities, while time, work, mass, etc., are scalar quantities.

Vector Addition and Subtraction. — Since vector quantities cannot be completely specified by ordinary numbers, the various operations of arithmetic such as addition, subtraction, multiplication and division have no meaning when applied to such quantities. Analogous processes, however, are of great value in dealing with them. For example, the resultant of two forces which make an angle with each other is, by the ordinary parallelogram of forces, equal to the diagonal of the parallelogram formed by drawing from the free ends of the two lines representing the forces, lines parallel to these forces. That is, the resultant of OA and OB in Fig. 1 is the diagonal OC. Both the length OC and direction (the angle AOC) of the resultant is fixed by this construction. The resultant OC is called the vector sum of OA and OB. Similarly, the vector sum of OA and AB is equal to OB, or vice versa, AB may be called the vector difference of OB and OA. The angle XAB gives the direction of this vector difference when OA is subtracted vectorially from OB. When OB is subtracted vectorially from OA the vector difference also has the same length or magnitude, but is in the opposite direction, i.e., makes the angle $180° - \angle XAB$ with OA.

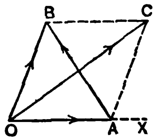

Fig. 1

Components of a Vector. — Any vector may be considered as made up of any number of vectors which when added vectorially, as described above, give a resultant vector equal to the given vector. It is frequently convenient in analyzing problems involving vectors to resolve each vector into two components, one parallel to and the other perpendicular to the axis of reference. The first component is usually referred to as the horizontal component and the second as the vertical component. It is readily proved that the horizontal component H of the resultant (or vector sum) of any number of vectors is equal to the algebraic sum of the horizontal components h_1, h_2, etc., of the individual vectors, i.e.,

$$H = h_1 + h_2 + \text{etc.}$$

and the vertical component V of the resultant is equal to the algebraic sum of the vertical components v_1, v_2, etc., of the individual vectors, i.e.,

$$V = v_1 + v_2 + \text{etc.}$$

The length of the resultant is then

$$S = \sqrt{H^2 + V^2},$$

and it makes with the axis of reference the angle σ where

$$\tan \sigma = \frac{V}{H}.$$

Analytical Representation of a Vector. — The geometrical representation of a complex quantity (*see Complex Quantities*) is a vector, i.e., the line representing a complex quantity has both magnitude and direction. Any vector quantity may, therefore, be represented by a complex quantity, and the operations of vector addition and subtraction may be carried out by the ordinary processes of algebraic addition and subtraction of complex quantities. For example, two vectors A and B may be represented by the algebraic expressions

$$\underset{\cdot}{A} = h_1 + jv_1,$$
$$\underset{\cdot}{B} = h_2 + jv_2,$$

where h_1 and h_2 and v_1 and v_2 are the horizontal and vertical components respectively, and the dots under A and B signify that $\underset{\cdot}{A}$ and $\underset{\cdot}{B}$ are vector quantities. The vector sum of $\underset{\cdot}{A}$ and $\underset{\cdot}{B}$ is then

$$\underset{\cdot}{S} = \underset{\cdot}{A} + \underset{\cdot}{B} = (h_1 + h_2) + j\,(v_1 + v_2),$$

which has the magnitude

$$S = \sqrt{(h_1 + h_2)^2 + (v_1 + v_2)^2},$$

and the angle

$$\sigma = \tan^{-1} \frac{v_1 + v_2}{h_1 + h_2}.$$

Multiplication and Division of a Vector by a Number. — Multiplying a vector by a real number n means taking a vector n times as long; dividing a vector by n means taking a vector $\frac{1}{n}$ of the length of the original vector. The result of multiplying a vector by an imaginary number jn is defined as a vector n times the length of the original vector and making a positive angle of 90° with the original vector. The result of dividing a vector by an imaginary number jn is defined as equivalent to multiplying the vector by $\frac{1}{jn} = -j\frac{1}{n}$ that is, as equivalent to a vector $\frac{1}{n}$ of the length of the original vector and making a negative angle of 90° with the given vector. Hence the multiplication or division of a vector $h + jv$ by a complex number $n + jn$ is equivalent to ordinary algebraic multiplication or division of two complex numbers (*see Complex Quantities*).

Scalar Product of Two Vectors. — Multiplication, in the ordinary sense, of one vector by another has no meaning, since a vector is not a number but involves both magnitude and direction. In the analysis of the more complicated problems of mechanics and electricity, certain expressions arise, however, which are analogous to ordinary multiplication. One of these expressions is a scalar quantity equal to the product of the magnitude of the two vectors by the cosine of the angle between them. This product is called the scalar product of the two vectors. The scalar product of the two vectors A and B is $AB \cos\theta$ where θ is the angle between them. If the vectors are expressed as complex quantities

$$\underset{\cdot}{A} = h_1 + jv_1,$$
$$\underset{\cdot}{B} = h_2 + jv_2,$$

the scalar product is

$$h_1h_2 + v_1v_2.$$

Note that this has no relation to the algebraic product of the two expressions $h_1 + jv_1$ and $h_2 + jv_2$.

Vector Product of Two Vectors. — Another expression which arises is a vector quantity at right angles to the plane of the two vectors and equal in magnitude to the product of the magnitudes of the two vectors by the sine of the angle between them. This product is called the vector product of the two vectors.

Example. — The vector product of the vector A by the vector B (Fig. 1) is $AB \sin \theta$, and is in the direction in which a right-handed screw, to the head of which A is conceived to be fixed, is advanced when A is turned through an angle of less than 180° into coincidence with B. From this definition it follows that the vector product of B times A is equal but *opposite* to the vector product of A times B. When A and B are expressed as complex quantities the vector product of A times B is

$$h_1v_2 - h_2v_1.$$

Note that the algebraic product of the expressions

$$h_1 + jv_1 \quad \text{and} \quad h_2 + jv_2 \quad \text{is} \quad h_1h_2 - v_1v_2 + j\,(h_1v_2 + h_2v_1).$$

The real and imaginary parts of this expression are *not* equal to the scalar and vector products.

[W. A. Del Mar.]

VISION, LAWS OF.— (*See also Illumination, Laws of; Photometric Quantities; Photometry.*) Light enters the eye through the *cornea*, a thin, transparent, curved wall, and passes successively through the *aqueous humor*, the *pupil*, the *biconvex lens*, and the *vitreous humor* to an image on the rear wall or *retina*. The cornea and lens possess the image-forming function, and accommodation to distance is given by the varying curvature of the lens. The humors give optical contact and preserve the size and form of the eye. The contraction and dilation of the pupil gives automatic accomodation to the intensity and quantity of light in the field of view. The retina comprises an elaborate structure of microscopic nerve terminals known as rods and cones. In its periphery rods predominate, but the ratio of cones to rods increases steadily toward the axial region of *fovea*, where the cones greatly predominate. The directly visualized image falls on the fovea and the sharpness of perception diminishes markedly in passing to the periphery. At very low intensities rod vision predominates. At moderate and high intensities cone vision predominates. In the former state the relative sensibility to the blue end of the spectrum is emphasized, in the latter state the relative sensibility to the red. As an optical system the eye has a chromatic aberration of approximately two diopters.

ELEMENTS OF VISION. — Visual sensations in general are characterized by intensity, extensity, quality and duration. Intensity refers to the aspects of vision measurable photometrically, as candle-power, brilliancy and illumination. Extensity involves the perception of contour, perspective, relief, detail and distance. Quality discriminates between sensations of color and non-color. Duration relates to the growth, fatigue, persistence and intermittency of visual sensations.

Intensity Relations. — All photometric units are essentially intensity measures of sensation. The luminous equivalent of radiation as determined by Ives (*see Phil. Mag., Vol. 24*) for the average eye is shown in Fig. 1. The lumens per watt scale shown is not final, but embodies the best available estimate. There is obviously no simple mechanical equivalent of light and the efficiency of light production depends to a marked degree on its spectral composition. Ives suggests two measures of luminous efficiency, viz., (1) the ratio of actual light emitted to that produced by the same power concentrated at the wave length of greatest luminosity, and (2) the ratio of the light emitted to that produced by the same power so distributed as to produce white light.

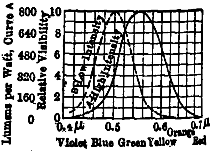

Fig. 1.

Purkinje Effect. — Transition from vision at low intensity to high involves relative loss of sensibility to blue and gain of sensibility to red, so that two lights of reddish and bluish hue respectively show a ratio of intensities which varies with the brightness of the field of view. This is known as the Purkinje effect. In fields above a brightness of one lumen per square foot the shift is slight. Photometric comparisons involving color differences should be made only in bright fields.

Sensibility. — The discriminating power of the eye for brightness, measured by the least perceptible percentage of increment, is practically constant at 1 per cent over a very wide range of intensity and is practically independent of color. Within this range the sensation of brightness varies as the logarithm of the stimulus. In so far as good seeing is a matter of perceiving differences in brightness the effectiveness of illumination does not increase in direct ratio to its intensity, but in a logarithmic ratio. It follows that if a

reasonable minimum of field brightness is maintained, say from one to two lumens per square foot, the gain from more intense illumination though real is relatively small.

Extensity Relations. — Extensity is perceived largely through differences in brightness and color, by varying visual angles and by acuity, or the power of resolving detail. Acuity follows a logarithmic relation to brightness similar to the strength of sensation. The same practical lower limit, say from one to two lumens per square foot, affords a fair normal basis of acuity. Above this the gain in acuity is relatively much less than the increase in illumination. Acuity, however, is not independent of color, due to the chromatic aberration of the eye. Retinal images formed by approximately monochromatic light are sharper than those due to a rich spectrum. Luckeish (*see Elec. W., Vol. 58, p. 1252*) gives the data in Fig. 2 for the relative acuity with various colors. For near vision blue light is more readily focussed, whereas for distant vision red light is more readily focussed.

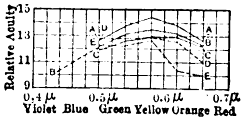

Fig. 2.

Glare. — The effectiveness of illumination is depressed to a marked degree by disturbing influences grouped under the term glare, which may be approximately defined as the relative overbrightness of part of the field of view. Transient glare, caused by the slowly changing adaptation of the eye when emerging from a dim region into a brilliantly lighted one, causes only temporary discomfort. Persistent glare, in addition to the depression of visual functions, may be highly injurious. No complete quantitative analysis of glare has yet been made. The following qualitative relations have been well established:

(*a*) Glare effect, or reduction of visual effectiveness, increases as the glaring source approaches the eye. Glare increases as the ratio of the distance of the glaring source to that of the visualized object from the eye diminishes. The distance at which a light source ceases to be glaring depends on its intensity, brilliancy and position in the field of view.

(*b*) Glare increases with the quantity of light received from the source.

(*c*) Glare increases with the brilliancy of the glaring source and with its degree of contrast to objects visualized. An automobile headlight is exceedingly glaring at night, but not glaring by day. Any light source giving an after-image is excessive in brilliancy. Glare due to this cause is accentuated by the reflex tendency of the eye to wander from the object of vision and fix on the brilliant source, causing a fatigue of attention.

(*d*) Glare increases as the retinal image of the glaring source approaches the center of the field of view. Depression of vision from side light is due in part to contrast and in part to the dilution of the central image by light scattered in the eye. Glare due to bright walls and backgrounds is largely of the latter class. The glare from bright sources situated at an angle from the line of vision exceeding 26 degrees is generally negligible.

The chief practical cases of glare are due to directly visible light sources of high power and brilliancy, to scattered light from side sources and backgrounds and the direct reflection of bright images by glazed surfaces in the immediate field of view. Prevention should be sought by the proper location and shading of light sources, by creating suitable constrasts between the field and its surroundings and by avoiding the use of glazed surfaces, especially highly-sized paper.

Duration. — Below certain frequencies intermittent sensations retain a measure of distinctness and produce a flicker effect. If a critical frequency is exceeded the sensations blend into a continuous effect equal in intensity to the

mean intensity over the complete cycle. Examples are the rotating sectored disk and the electric lamp operated by alternating current. The vanishing frequency of flicker increases with the degree of variation from maximum to minimum, with the solid angle subtended by the object viewed, and with the intensity of its brightness. The vanishing frequency of flicker is higher for white than for colored light. Within the common limits of practice the vanishing frequency is between 30 and 45 cycles per second. Electric lamps display no observable flicker in themselves or in illuminated objects at frequencies exceeding 40 cycles.

Quality or Color Relations. — Non-colored sensations are white, gray and black. Color sensations differ in brightness, in hue and in tone. The hue of a light is determined by the spectral position of its predominant component. Its tone or tint depends on the degree of dilution with white or black. Thus spectral red, pink and claret may agree in hue, but differ essentially in tone. Color sensations are equal in brightness when they may be rapidly alternated in the field of view without the appearance of flicker.

Synthesis of Colors may be accomplished by mixing red, green and blue in proper proportions, or by diluting the predominant hue with the proper amount of white or black. A color may be specified by the synthesis necessary to reproduce it. Tri-chromatic specification gives the mixing proportions of red, green and blue. Mono-chromatic specification gives the spectral hue and the degree of dilution. The tri-chromatic analysis as determined by the colorimeter (*see Photometry*) is of greatest practical utility. In this system the proportions of red, green and blue found in average daylight, though not equal, are taken as 33.3 per cent each to fix three color scales. The mixing proportions of these colors on the scales so established which reproduce any given light serve to specify it and to compare its color composition with daylight. Ives gives the following color analyses of common light sources.

Source	Red	Green	Blue
Black body at 5000° F. abs. (white)	33.3	33.3	33.3
Overcast sky	34.6	33.9	31.5
Blue sky	32.0	32.2	35.8
Moore carbon dioxide tube	31.3	31.0	37.7
Afternoon sunlight	37.7	37.3	25.0
Mercury vapor arc	29.0	30.3	40.7
Direct-current carbon arc	41.0	36.3	22.7
Welsbach mantle, ¼% cerium	42.5	40.8	16.7
Welsbach mantle, ¾% cerium	45.5	42.0	12.5
Welsbach mantle, 1¾% cerium	47.2	41.8	11.0
Tungsten filament, 1.25 w. p. c.	48.7	40.5	10.9
Nernst glower	49.2	40.7	10.1
Acetylene flame	49.1	40.5	10.5
Yellow flame arc	52.0	37.5	10.5
Carbon filament, 3.1 w. p. c.	51.3	40.4	8.3
Hefner standard lamp	55.0	38.8	6.2

Relation of Color of Light to Appearance of Objects. — Objects appear in the colors which they reflect or transmit to the eye. To produce true color effects light must possess all the components necessary to reveal objects and possess them in proper proportions. If the spectrum is deficient in

parts or its components differ greatly from the proportions in daylight it will in general produce distorted color effects.

Artificial White Light. — With the exception of the carbon dioxide vacuum tube no artificial illuminant approaches closely the color value of daylight. White light may be approximated by synthesis by combining the light of two sources, one excessive in red and the other excessive in blue, as the incandescent electric lamp and the mercury arc. A closer realization may be obtained from any incandescent lamp by means of a selective absorption screen which removes the excess of red and green light. The latter method involves a large sacrifice of efficiency.

SUMMARY OF CONDITIONS FOR BEST VISION. — The surface brightness of objects viewed should not be less than 0.0015 candle per square inch nor more than 1.5 candles. In terms of the illumination of ordinary white paper these values correspond roughly to limits of 1 to 1000 foot-candles. The value best adapted to any condition varies with the individual, the closeness of application, the nature of the surroundings and the general degree of diffusion. For reading by daylight 100 foot-candles is approximately the best condition, by artificial light approximately from 4 to 10. The degree of illumination required is strongly influenced by the contrast between objects visualized and their surroundings. The high diffusion of daylight and the flatness of the contrasts which it gives account in large measure for the higher illumination desired. For best seeing the objects viewed should be brighter than the surroundings, but the contrast should not exceed 10 : 1. The illumination provided for work requiring close application should be in inverse ratio to the reflecting power of the predominant surfaces. Directly visible light sources may generally be shaded down to a brightness of 2.5 candles per square inch with advantage to vision. Precautions outlined under *Glare* should be observed.

The accompanying table indicates the range of artificial illumination in foot-candles which has been found satisfactory under practical conditions.

Location	Desirable illumination in foot-candles	Location	Desirable illumination in foot-candles
Auditoriums	1.5-3.0	Residences:	
Art-gallery walls	3.0-5.0	Living rooms	2.0-3.0
Corridors	0.5-1.5	Bedrooms	1.0-2.0
Desks	3.0-5.0	Halls	1.0-2.0
Drafting rooms	5.0-8.0	Basements	0.5-1 0
Factories:		Restaurants	2.0-3.0
General lighting	1.0-2.0	School rooms	3.0-4.0
Specific lighting	4.0-6.0	Signs	2.0-3.0
Games and amusements:		Show windows:	
General	1.5-3.0	Dark goods	20-30
Specific	4.0-5.0	Medium goods	12-25
Laboratories	3.0-5.0	Light goods	8-15
Passenger cars	2.0-3.0	Stores and show rooms:	
Postal service	4.0-6.0	Dark goods	5-8
Reading rooms	3.0-4.0	Medium goods	3-5
		Light goods	2-4

Definition. — Vision is aided by the sharp definition of details down to an angular range of 1 in 10,000. Reading is easiest with type subtending an angle of about 1 in 100. For comfort it should not be larger than 1 : 20 nor less than 1 : 300.

Contrasts in intensity are best at about 1 : 10, but should not be less than 1 : 100. Contrasts as slight as 98 : 100 are readily perceivable in good light.

Uniformity of light on the working area is important. Excessively bright spots constitute an annoying glare and interfere with the fixation of vision.

Steadiness of light is essential, as flicker causes rapid fatigue.

Color. — A well-balanced spectrum is required for the true revelation of surface colors. Fatigue is most rapid in the extreme blue end of the spectrum and ultra-violet radiations may cause injury if present in unusual quantity. Light having a strongly dominant yellow-green hue gives the highest visual acuity.

Diffusion. — Complete diffusion tends to eliminate shadows, with the resulting loss of relief. The value of moderate shadows varies greatly with the circumstances, but is greatest where color distinctions are lacking.

VISUAL EFFICIENCY. — The resultant of all conditions affecting vision is included in the somewhat loose term visual efficiency. This concept must take account of the fundamental discriminations of brightness, detail and color and of the maintenance of these faculties in use. Tests of visual acuity have been largely used as a working criterion of visual efficiency. As applied to the momentary state of vision this criterion is unsatisfactory as it invites a semi-conscious mental spur to offset fatigue. An ideal criterion must take account of the maintenance of acuity in work, of the ease with which fixation of vision and attention are sustained, and of the general requirements of ocular hygiene. (*See Trans. Ill. Eng. Soc., Vol. 8, p. 40.*)

[W. E. WICKENDEN.]

VOLTMETERS. — (*See also Ammeters; Wattmeters.*) A voltmeter is an instrument for measuring the potential difference, or voltage, between the two points to which its two terminals are connected. Any type of ammeter (q.v.) may be used as a voltmeter, but when designed for this purpose the coil which carries the current is made of a number of turns of fine wire, so that the moving element will be deflected by a very small current (from 10 to 200 milliamperes for full-scale deflection, depending upon the type of meter) and to limit the current to this value a high resistance, contained within the case of the instrument, is usually inserted in series with the coil. The high resistance may be provided with taps brought out to additional binding posts, so that the same instrument will give full-scale deflection for say 75, 150 and 300 volts, depending upon which binding post is used in conjunction with the terminal marked "0" or "+." The range of a voltmeter may also be indefinitely extended by the use of multipliers (*see below*) or potential transformers (*see Transformers, Instrument*).

Current Taken by, and Resistance of, Voltmeters. — The current taken by voltmeters of various types for full-scale deflection, and the resistance per volt of full-scale deflection are usually as follows:

Type of voltmeter	Milliamperes for full-scale deflection	Ohms per volt of full-scale deflection*
Moving magnet type	83 to 60	12 to 17
Iron-vane type	83 to 60	12 to 17
Moving-coil type	10	100
Electrodynamometer type	83 to 40	12 to 25
Hot-wire type	250 to 187	4 to 5.3

* For example, an iron-vane type voltmeter having a 150-volt scale would have a resistance of from $12 \times 150 = 1800$ to $17 \times 150 = 2550$ ohms. The resistance corresponding to a 15-volt scale would be from 180 to 255 ohms. The current taken by the instrument for either scale would be from 83 to 60 milliamperes.

Temperature and Inductance Errors. — In order that a voltmeter calibrated at one temperature shall read correctly at all other ordinary temperatures, it is necessary that the total resistance within the instrument shall not change appreciably with change in temperature, due either to variations in room temperature or to the heating of the windings by the current. To secure this condition, the resistance included in series with the active winding (which is usually made of copper wire) must have a practically negligible temperature coefficient. Various alloys may be used for this purpose; see *Wires, Resistance.* Precision voltmeters are sometimes provided with a thermometer, with the bulb within the case, and a small adjustable resistance to compensate for change in resistance due to temperature variations.

The high resistance within an a-c. voltmeter is wound non-inductively, i.e., the wire is doubled back on itself before being wound on the spool, or otherwise suitably arranged; the total impedance of the meter is then practically equal to its total resistance, and consequently its indications are affected but slightly, if at all, by the frequency of the voltage, at least up to 100 or 125 cycles per second. Some voltmeters of the soft-iron vane type, however, should be calibrated with voltage of the same frequency as that of the circuit on which they are to be used; for explanation see article on *Ammeters.*

Multipliers and Potential Transformers. — A voltmeter multiplier is simply an external resistor placed in series with the voltmeter. These resistors are made of high-resistance alloys having a low temperature coefficient, and are wound non-inductively. Let

r = resistance of voltmeter, in ohms,
R = resistance of multiplier, in ohms,
v = value of 1 scale division in volts without multiplier,
V = value of 1 scale division in volts when a multiplier having a resistance R is used.

Then

$$V = \frac{R+r}{r} \cdot v,$$

or the multiplier multiplies the voltmeter reading by the fraction $(R+r)/r$. This ratio is frequently called the "multiplying power" of the multiplier for the voltmeter in question.

For voltages above 750 volts potential transformers are to be preferred to multipliers for a-c. circuits; see *Transformers, Instrument.*

Low-voltage A-C. Voltmeters. — In voltmeters for measuring small alternating voltages the extra resistance in series with the active winding must necessarily be small or eliminated entirely for the lowest voltages, in which case the errors due to inductance, heating and change in room temperature may be quite large, 1 per cent to 3 per cent or even larger. When the voltmeter may be permitted to take a larger current than that given in the above table, without interfering with the actual voltage to be measured, a special low-resistance voltmeter may be used having a total resistance much lower than that of the ordinary voltmeter, the resistance of the active winding and the external resistance being reduced in the same proportion. For usual switchboard service and large power work satisfactory instruments of this kind may be had, giving a full-scale deflection for 15 volts or less.

Electrostatic Voltmeters. — When the current taken by the ordinary form of voltmeter is an appreciable fraction of the load current or when the frequency is very high, as in wireless work, an electrometer (*see article on Electrometers*) or electrostatic voltmeter may be used. The ordinary electrostatic voltmeter is in principle the same as an electrometer, but is provided with a pointer and scale and is so constructed as to be more readily portable than the ordinary electrometer which is read by means of a telescope and scale. Repulsion electrostatic voltmeters are also used, the principle of operation being the repulsion of two conductors charged with electricity of the same sign, as in a gold-leaf electroscope.

Condenser multipliers are sometimes used with electrostatic voltmeters; see *Electrometers*.

Calibration of Voltmeters. — A voltmeter may be calibrated by comparing it with a standard voltmeter whose calibration curve is known, or it may be calibrated directly by means of a potentiometer and standard cell; see *Potentiometers*. Hot-wire and electrodynamometer voltmeters for alternating-current work are calibrated on direct or alternating current; an iron-vane voltmeter should be calibrated by comparing it, on alternating current, with one of the other types which has been previously calibrated on direct current. Electrostatic voltmeters are usually employed commercially only for high voltages, and therefore must be calibrated on alternating current.

Precautions in Use and Installation, Costs, Bibliography, etc. — See the article on *Ammeters*.

[L. T. Robinson.]

WATER WHEELS AND THEIR SETTINGS.* — (*See also Hydraulics, Principles of; Power Stations, Hydroelectric; Water Wheels, Speed Regulation of.*) A water wheel is a machine for converting the energy of falling water into mechanical work.

CLASSIFICATION. — The old-fashioned under-shot and over-shot wheels (see any dictionary) are now seldom used, although a few over-shot wheels of very high efficiency have been constructed recently. Modern wheels may be classified as (*a*) impulse wheels (*b*) reaction wheels and (*c*) turbines.

Impulse Wheels are those in which the energy of the water is transformed into kinetic energy before reaching the wheel. The water is usually directed against the wheel in a single jet. The line of demarcation between turbines and impulse wheels is not sharply drawn.

Reaction Wheels are those in which the work is done by the reactive energy of the jets of water as they issue from the wheel.

Turbines may be defined as water wheels in which the energy of the water is gradually transformed into kinetic energy as it passes through the guides and wheel. Turbines in general have a series of curved moving vanes called "buckets" around their circumference into which the water is directed through curved "guide vanes." These vanes are so proportioned that they first transform the energy of the water into kinetic energy and then use this kinetic energy in driving the wheel. The following classification depends upon the action of the water:

Reaction Turbines are those in which the energy of the water is transformed into kinetic energy partly in the guides and partly in the wheel. They must run full of water and may be submerged without greatly reducing their efficiency.

Impulse Turbines are those in which the energy of the water is transformed into kinetic energy wholly in the guides. The wheel may run partially empty without particularly affecting the efficiency. The discharge must be into the atmosphere. If the wheel becomes submerged a great loss of efficiency takes place.

Limit Turbines which are on the dividing line between impulse and reaction turbines and may act efficiently as either.

Turbines may be classified also in accordance with the direction of flow as (*a*) radial flow, either outward or inward, (*b*) axial flow (parallel to the shaft) and (*c*) mixed flow, in which the flow is partly radial and partly axial. Again, they may be classified in accordance with the position of the wheel shaft as (*a*) vertical and (*b*) horizontal. Again, they may be classified according to whether the nozzles or guides extend partially or entirely around the wheel as (*a*) complete turbines and (*b*) partial turbines.

APPLICATIONS OF VARIOUS TYPES. — The following is intended to serve as a broad general guide in the choice of the particular type of wheel for a given set of conditions. It is to be understood that these rules are subject to considerable variation under varying conditions.

Impulse Wheel to be used for high heads and small quantities of water.

Reaction Turbine to be used for all heads and large quantities of water when the flow is fairly uniform at all times.

* Much of the information in this article is from the S. Morgan-Smith Co., manufacturers of wheels, who also furnished most of the drawings from which the cuts were made.

Impulse Turbine to be used for high heads and large quantities of water when flow is variable.

Setting and Position for Various Heads. — The methods of setting and style of wheel used (whether horizontal or vertical) under different conditions are about as follows:

Up to 12 ft. Head. — Vertical wheels in open or closed flumes are used.

12 ft. to 30 ft. Head. — Either horizontal or vertical wheels are used, more often horizontal; either open or closed flume is used, more often open.

30 ft. to 90 ft. Head. — Usually horizontal wheels in steel cases are used, sometimes in concrete cases.

90 ft. to 600 ft. Head. — Either horizontal or vertical wheels are used, more often horizontal, usually in a cast-iron scroll case.

DESIGN AND CONSTRUCTION. — The actual design of the details of the guides and runners is too complicated and involved to be treated here in detail. Certain general principles should be observed of which the most important is that the shape of the guides and runners should be such that the water will enter the wheel without shock and leave without velocity. It is possible to fulfil the first condition very closely. The last can only be approached because the leaving water must have velocity enough to carry it away from the turbine. The design of American turbines has been largely the outgrowth of some 70 years of practical experience and tests.

Runners. — The runner is the revolving part that directly transforms the energy of the water into mechanical work. It is either cast solid or built up. The parts of a runner are the hub, the crown, the ring, and the buckets or vanes. Fig. 1 shows a typical runner. All parts of the wheel, but more especially the buckets, must be smooth and free from projections, as all inequalities of surface in a flowing stream of water cause appreciable losses of energy. For this reason the majority of cast wheels are made in one solid casting of soft iron to reduce shrinkage stresses; cast steel or bronze wheels are also used for high heads. The buckets may also be cast separately and afterward put in a mold and the hub, crowns and rings cast about them. The curve of the buckets may be almost any smooth curve which will direct the water backward sufficiently relative to the wheel as it leaves.

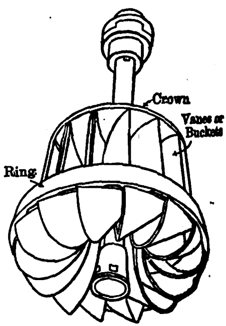

Fig. 1. Typical Runner

Diameter of Runners. — Reaction runners are measured at inlet. For buckets like Fig 2A this is simple. Buckets are often however cut back as shown in Fig. 2B to give greater speed and capacity. The buckets are usually tapered as shown. Different manufacturers measure and list their wheels at different points. This lack of uniformity in practice partially accounts for apparent variations between wheels of the same nominal size made by different manufacturers. Mead's *Water Power Engineering, p. 256,* gives a table showing the practice of some American manufacturers in measuring and listing their wheels.

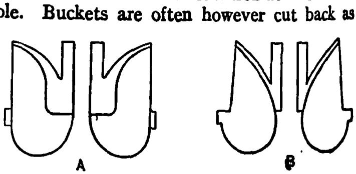

Fig. 2. Typical Bucket (after Mead)

Peripheral Speed of Runner. — The efficient speed of a wheel depends upon the ratio of the peripheral velocity of the wheel to the spouting velocity of water under the working head. This spouting velocity is equal to $\sqrt{2gh}$ where h is the working head and g is the acceleration due to gravity (32.2 feet per sec.^{2}). The ratio is practically 0.50 for impulse wheels; for reaction turbines it ranges from 0.65 to 0.95; for impulse turbines it ranges from 0.40 to 0.50.

Bearings. — The bearings in a turbine are often subjected to axial thrust and are quite often located of necessity in inaccessible places, and are sometimes even submerged. The forces causing thrust are (1) a reaction from the flowing water which acts in a direction opposite to the flow, and is of importance only in turbines which discharge axially and in one direction; and (2) thrust due to leakage into the space back of the runner, which may be relieved by leaving holes in the runner close to the shaft. In large turbines these pressures are carefully provided for and a thrust bearing is used to take care of them. In all but the large vertical units a simple step bearing, consisting of a lignum vitæ block located at the bottom of the shaft, is generally used. Wood is used because of the difficulty of lubricating a bearing in water. Wet wood is quite slippery and when hard enough to wear very slowly makes an excellent submerged bearing. A bearing of the ordinary type above the turbine serves to keep it in alignment. In some turbines the runner is suspended from above. The suspended type of bearing is easier to lubricate and to inspect but is more expensive than the step bearing. When twin horizontal turbines are used they are located on the shaft so that the water flows through them in opposite directions. The thrust on each wheel is balanced by that on the other. It is usual to provide a thrust bearing in such a case so that one turbine may be operated if necessary without the other.

Chute Case. — The chute case is the fixed portion of the turbine to which the bearings, guide vanes, and gates are attached. It surrounds the wheel and in it are formed the lower end of the penstock and the upper end of the draft tube. The chute case is generally made of cast iron or cast steel and sometimes of steel plates riveted together. The cast case is preferable because the passages, which are usually more or less curved, can be cast much more readily than they can be shaped in plates. The plates have the further objection of the obstruction caused by the rivet heads. In the most up-to-date practice a scroll case is used. It is so constructed that the cross-sectional area of the case decreases gradually as the water leaves the case to enter the wheel. This keeps the water moving at a constant velocity at all points in the case, which results in its entering the wheel with the same velocity at all points on its circumference and also obviates eddies and foam in the case. It is one of the important elements which influence the efficiency of the wheel.

Gates. — Three forms of gates are used in connection with reaction turbines, viz., the cylinder gate, the wicket gate, and the register gate. The cylinder gate is the cheapest and the wicket gate is best when properly designed and constructed.

Cylinder Gate. — This gate is a cylinder closely fitting the guides and located between them and the wheel. It moves parallel to the axis of the turbine and controls the admission of water by its position. This type of gate is sometimes used over the discharge. A gate of this type when partially closed causes a sudden contraction and expansion of the stream of entering water. This causes eddying and consequently decreased efficiency of the turbine at part gate.

Wicket Gate. — This type of gate, which is illustrated in Fig. 3, is very satisfactory. The quantity of water admitted is regulated by rotating each

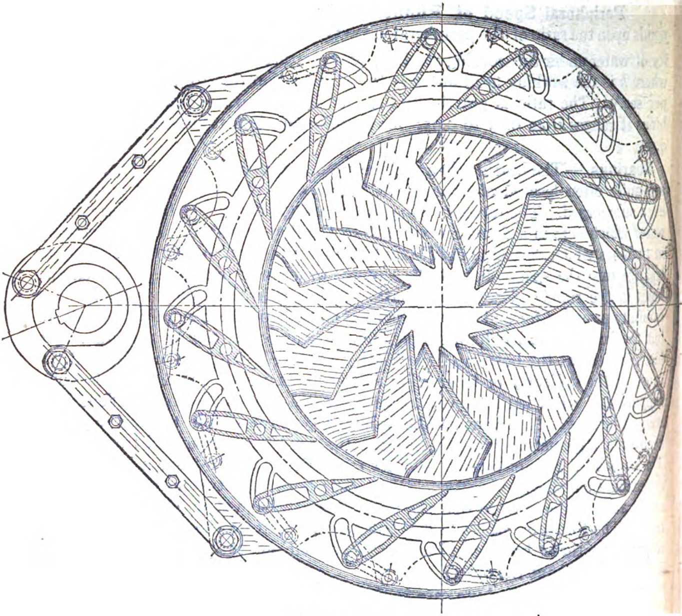

Fig. 3. Wicket Gate

wicket or "slat" about its axis so that the cross-sectional area of the passage through the guides is reduced. The wickets are connected together so that all are operated at once. Eddying is much reduced with this type of gate.

Register Gate.—This gate is a cylindrical case with openings in it to correspond with those in the guides. When running at full gate the openings in gate and guide register. By rotating the gate about the axis of the turbine the openings can be partially or wholly closed as desired. There is considerable eddying and consequent decreased efficiency under part gate.

Gates for Impulse Turbines.—These are often arranged so that the guide passages are opened one at a time. This causes less loss due to eddying at part gate.

Nozzles for Impulse Wheel.—In the tangential impulse wheel the best method for varying the opening is with a needle nozzle. When properly designed such a nozzle gives a very high velocity coefficient under a wide range of opening.

The Draft Tube.—The draft tube is in principle a suction pipe attached to the discharge of the turbine with its end submerged in the water of the tail race. It enables the full difference in head between the fore-bay and the tail-bay to be utilized. If the draft tube is not used it is still possible, with a reaction turbine, to utilize the full head by submerging the wheel. The submerged wheel is difficult of access for repairs and is likely to be injured by ice in case of a shutdown in weather cold enough to freeze the water in the tail-bay. The water in passing through the draft tube exhausts the air from it and the

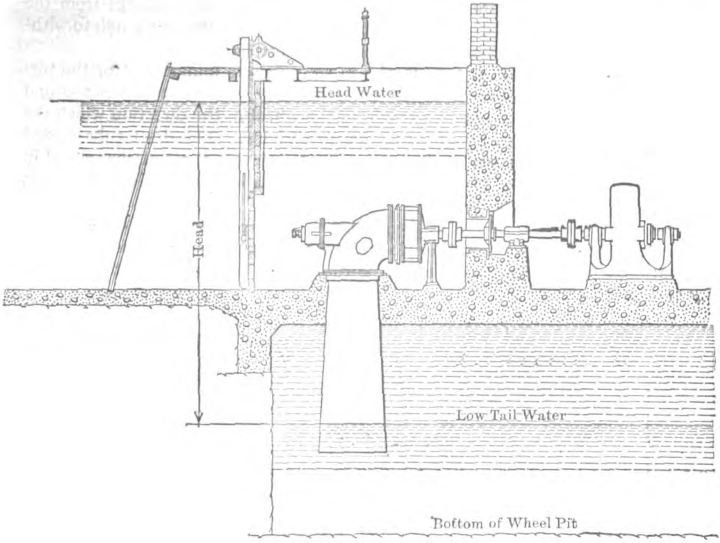

Fig. 4. Open-flume Setting for Horizontal Turbine

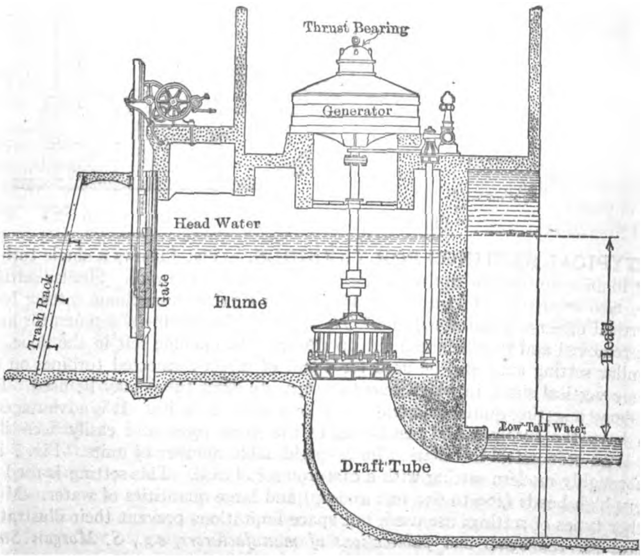

Fig. 5. Open-flume Setting for Vertical Turbine

column of water in the tube then exerts a suction on the discharge from the wheel. A vacuum exists in the draft tube and it must be strong enough to withstand the collapsing pressure of the atmosphere upon it.

In many plants the draft tube is cast in the concrete foundation for the turbine. Water should leave the wheel with a velocity of about 1.5 ft. per second and the draft tube should start away from the wheel in the direction which the water takes, in order to avoid losses due to eddying. The draft tube should gradually enlarge to as great a diameter as is practicable at its discharge end in order to reduce the velocity head as much as practicable, which in turn increases the head available at the wheel.

The draft tube should not be longer than about 20 feet, both because it is difficult to hold the vacuum in a longer tube under the varying conditions of operation, and because the water in the tube is apt to surge when the position of the gate is changed.

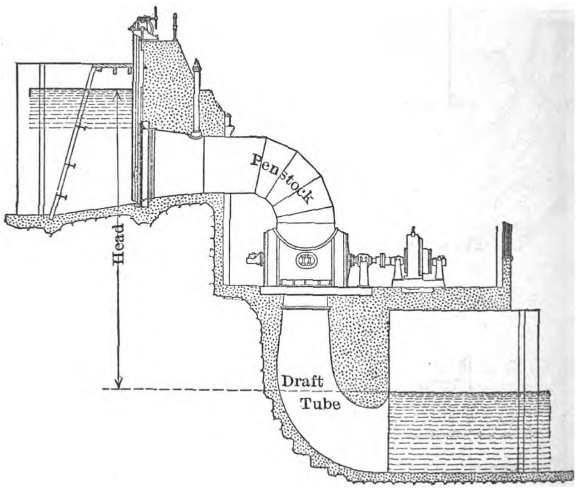

Fig. 6. Common Form of Setting

TYPICAL SETTINGS FOR TURBINES.—Fig. 4 shows a single turbine set in an open flume with the shaft extending through the wall. Similar settings are also used for twin turbines. Fig. 5 is a typical open flume setting for a vertical direct-connected turbine. To take out the turbine the generator must be removed and the turbine lifted up through the opening left in the floor. A similar setting may also be used for a pair of direct-connected turbines on the same vertical shaft, in which case two separate draft tubes may be used. Fig. 6 shows a setting quite commonly used for a series of units. It is advantageous to have the turbines and generators in the same room and easily accessible. It is an economical installation for a considerable number of units. Fig. 7 is a thoroughly modern setting with a cast-iron scroll case. This setting is used for very high heads (400 to 600 feet and up) and large quantities of water. Many other types of settings are used, but space limitations prevent their illustration here; see *catalogues and publications of manufacturers, e.g., S. Morgan Smith Co., Holyoke Machine Co., etc.*

TESTING OF WATER WHEELS. — The only practicable way to test a turbine is after it is set up and ready to run. The object of the test is to determine efficiency (ratio of output to input) under different conditions of gate opening and load. To determine input the head and quantity of water flowing must be known. In computing the efficiency of the turbine it is not fair to take the head as the difference in level between the fore-bay and the tail-bay because the water must have some velocity in order to escape from the turbine. The velocity head corresponding to the velocity of the water at the exit to the draft tube should be subtracted from the difference in level between the fore-bay and the tail-bay. The difference in level between the pond and the fore-bay should not be charged against the turbine as this is a loss incurred in bringing the water to it.

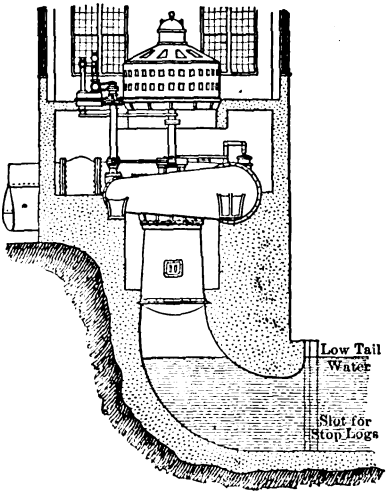

Fig. 7. Setting with Scroll Case

Determination of Input. — The greatest difficulty in testing lies in determining accurately the quantity of water which flows through the turbine. For this purpose a Pitot tube may be inserted in the pipe or a current meter may be used to measure the velocities at different points on a cross-section of either the fore-bay or tail-bay; the Pitot tube and current meter are described in the article on *Hydraulics*. Multiplying the average velocity in ft. per min. on a cross-section by the area of the cross-section will give the cu. ft. per minute. This quantity multiplied by the head and by 62.4 (the weight of a foot of water) and divided by 33,000 will give the horse-power input.

In some cases, when a penstock is used, it has a Venturi meter (*see Hydraulics*) built in it. This gives an excellent means of determining accurately the quantity flowing. This meter is not accurate below 20 per cent of its rated capacity, but results of tests below that point are seldom desired.

Determination of Output. — The horse-power output up to 1500 horse-power is best determined by means of an Alden brake; this is a special form of water-cooled Prony brake (*see Index*). If the turbine is connected to a generator the losses in which are known the generator may be used to measure the output.

Example of Test. — The appended table gives the results (for a number of points) of a complete test of a 33-inch special Smith turbine made by the S. Morgan Smith Co., who have kindly permitted its use. The test was made at the Holyoke Testing Flume, Holyoke, Mass. Study of the test shows that the highest efficiencies occur at about 0.8 gate opening. This is as it should be, because when there is abundant water and the wheel is running at full gate the efficiency is not so important as it is when running at part gate with a more or less restricted flow of water. Under the latter circumstances as much power as possible must be obtained from every cubic foot of water. Moreover, under

(PARTIAL) REPORT OF TESTS OF A 33-INCH L. H. SPECIAL SMITH TURBINE WHEEL (August 14-15, 1913)

NOTES. — The turbine and dynamometer carried during test on ball-bearing step. With the flume empty a strain of 3 lb., applied at a distance of 3.0 ft. from the center of the shaft, sufficed to start the wheel.

ordinary conditions the load should be such that somewhat less then full gate opening will take care of it, thus leaving something in reserve for a sudden excess demand upon the wheel. This is an exceptionally efficient wheel giving an efficiency of 90.2 per cent under certain conditions.

Usual Efficiencies. — A water wheel is usually designed so that the maximum efficiency occurs at about 80 per cent gate opening. For tangential wheels this maximum efficiency is usually from 75 to 85 per cent and for reaction turbines from 80 to 85 per cent. The test given in the preceding paragraph shows much higher efficiencies than usually obtained, the wheel in this case being an unusually good one.

COST OF WATER WHEELS. — The following figures give some idea of the cost of the different sizes of wheels exclusive of settings, except as noted; the necessary pulleys and gears are included. Freight and cost of installation not included. The cost per horse-power, which varies from $2 to $20, decreases both as the head and the size of the unit increase. See also article on *Power Stations*.

Style of wheel	Head, feet	Horse-power	Cost per horse-power
Vertical, open flume	10	100	$ 8.00
Same except with steel case and steel supports	10	100	13.00
Pairs of horizontal wheels in open flume.	20	500	7.00
Same conditions, steel case	20	500	10.00
Pairs of horizontal wheels, open flume	40	5000	5.00
Horizontal wheel, single runner, cast-iron scroll case	90	1400	6.00
Horizontal or vertical single-wheel cast-iron scroll case	200	5000	2.00 to 3.00

BIBLIOGRAPHY. — A complete bibliography up to 1908 is given in Mead's *Water Power Engineering*. Among the books in English there listed may be noted Church, I. P., *Hydraulic Motors*, N. Y., 1905; Thurso, J. W., *Modern Turbine Practice*, N. Y., 1905; Wood, DeV., *Turbines, Theoretical and Practical*, N. Y., 1901; Horton, R. E., *Turbine Water Wheel Tests, Water Supply and Irrigation Paper*, No. 180, *U.S. Geological Survey*, 1906. Some more recent books on water wheels are Russell, G. E., *Text Book on Hydraulics*, N. Y., 1912; Daugherty, R. L., *Hydraulic Turbines*, N. Y.; Gelpke and Van Cleve, *Hydraulic Turbines*, N. Y., 1911; Von Schon, H.A.E.C., *Hydro-electric Practice*, Phila., 1908; Koester, F., *Hydroelectric Developments and Engineering*, N. Y., 1909; Lyndon, L., *Development and Electric Distribution of Water Power*, N. Y., 1908. A.I.E.E., March, 1913; *The Runaway Speed of Water Wheels*, Trans. A.I.E.E., June, 1912; *Selection of a Water Wheel Unit*, Trans. A.I.E.E., Apr., 1912; Several articles in the *Jour. Elec. Power and Gas*, 1911 and 1912.

[L. E. MOORE.]

WATER WHEELS, SPEED REGULATION OF.* — (*See also Hydraulics; Power Stations, Hydroelectric; Water Wheels and Their Settings.*) In a few special cases close speed regulation of water wheels is unnecessary, for example, in pulp grinding, certain chemical processes and operating air compressors. Even in these cases experience has shown that better results may be obtained when wheels are controlled by properly designed governors. For factory work, where the power is applied through the medium of belting, the problem of regulation is simplified by the large inertia effect of the pulleys and belting.

SPEED VARIATION IN HYDROELECTRIC PLANTS. — For electrical generators, which perhaps comprise the majority of installations, the utmost nicety of speed regulation is required because the value of the electrical energy produced is greatly lessened if the voltage and frequency are not uniform. In the best large modern power plants speed variations greater than one or two per cent are exceptional. In smaller plants, since there are usually larger proportional load fluctuations, it is more difficult to maintain close speed regulation.

Calculation of Speed Regulation. — When the gates are controlled by a governor (*see below*) the percentage change in speed of the wheel due to a change in load, when the penstock, if any, is short, is given approximately by the formula:

$$s = 81{,}000{,}000 \frac{TL}{IN^2},$$

where

s = percentage change in speed,
T = time required to reset gates, in seconds,
L = change in load, in horse-power,
I = flywheel effect of wheel and generator, in foot and pound units, i.e., I is the weight in pounds which at a radius of one foot would have the same moment of inertia as that of the wheel and generator combined,
N = number of revolutions per minute.

When the penstock is long, the calculation is more complicated; see section below under *Long Penstocks and Auxiliary Devices.*

DIFFICULTIES OF REGULATION. — In an open flume installation under low heads the regulation is a very simple problem. Where the water is conducted to the wheel through a long pipe, or penstock, regulation becomes a very serious matter. Regulation is effected, in general, by varying the quantity of water flowing to the wheel. This requires a change in the velocity of the water flowing in the penstock, when one is used.

The difficulty of regulating turbines at the end of long pipe lines becomes less in proportion as the flywheel effect per horse-power becomes greater, because an increase in the flywheel effect permits slower governor action for a given per cent change in speed. A slow governor action insures slower acceleration and retardation of the water column, and consequently smaller pressure changes. The necessity for large flywheel effects for a given head is greater the less the slope of the pipe line.

A successful *governor must anticipate the effect* of any gate movement. It must move the gate to, or only slightly beyond, the position which will give normal speed when the flow in the penstock has become adjusted to the new conditions. The gates are heavy and not infrequently bind; hence moving them with certainty and precision requires a powerful governor.

* The material for this section was obtained from Mr. Henry E. Warren, *Consulting Engineer* of the Lombard Governor Co., Ashland, Mass.

METHODS OF REGULATING. — Under small heads the regulation is easily and safely accomplished, and depends almost solely upon the power and sensitiveness of the governor. Under large heads the practical impossibility, in most cases, of safely changing the velocity of the water column with the requisite quickness leads to various expedients. With impulse wheels a "deflecting nozzle" (*see below*) is used in connection with a needle valve. In all turbines the regulation is accomplished by moving the gates. The difficulties met with in connection with high heads are taken care of by auxiliary devices which operate in conjunction with the governor. They may or may not be operated by mechanical connection with the governor. The devices are: (1) by pass valves, (2) relief valves, (3) stand pipes, (4) surge tanks, all of which are treated below.

WATER-WHEEL GOVERNORS. — The governor proper is the device for automatically opening and closing the gates as the load on the wheel varies. The requirements to be met are (1) sensitiveness to small variations in speed, (2) quickness in action, (3) steadiness and accuracy in moving the gates the proper amount, (4) ability to operate continuously with minimum amount of attention.

Types of Governors. — There are two general classes of governors; (1) the "mechanical" type, which takes energy from the water wheel itself, as required, through a belt or gearing, and by means of friction clutches applies this energy at suitable times to the operation of the water-wheel gates; (2) the "hydraulic" type, in which stored energy in the form of compressed air is made available when required to move the water-wheel gates through the medium of liquid acting against the piston in a hydraulic cylinder. The energy in the compressed air is thus transmitted by the liquid through a suitably controlled valve to do the work of moving the water-wheel gates, when necessary, and the energy of the air is afterwards restored by pumping the same liquid back into the air tank. The operation of restoring the energy by pumping is gradual; while the operation of moving the water-wheel gates, by utilizing the energy of the compressed air, may be as rapid as desired.

Governors of the mechanical type were the first in the field, and, being simpler and cheaper to construct, have been very widely used. They have certain objectionable features, however, which have prevented them from being adopted under any conditions which require extreme nicety in speed regulation. Consequently, governors of the hydraulic type are almost exclusively used in large and important power plants. When properly designed, they are capable of giving extremely accurate speed regulation and are thoroughly reliable. Such governors are sometimes operated continuously night and day for weeks, or even months.

Connections Between Wheel and Governor. — The connections between a water-wheel governor and the gates of a turbine must be strong, direct and free from lost motion; otherwise the governor cannot perform its functions properly. Governors are built nowadays in many different types, so as to be readily adapted for connections to any standard make of turbine. It is always desirable to submit plans of the water wheels, with surrounding portions of the power plant, to the governor builder so that the two machines may be fitted together to the best advantage. It is generally advantageous to have the hydraulic cylinder of the governor located near the water-wheel gates, although for very large units the control mechanism of the governor may be more conveniently placed on the floor above. For small water wheels, which are occasionally located in comparatively inaccessible places, it is sometimes necessary to place the governors at a considerable distance and connect them with the water-wheel gates by means of special flexible steel cable. Occasionally several water wheels are connected in this manner to a single governor.

Distant Control. — Large governors are frequently provided with suitable electric devices by means of which the speed of the wheel may be adjusted from any distant point, thus permitting alternators driven by independent water wheels being brought to the same speed and angular position for multiple connection.

Rating of a Governor.— A hydraulic water-wheel governor is usually rated in terms of the energy, expressed in foot-pounds, which is developed by one stroke of the piston, and the time, in seconds, required for a complete stroke (i.e., to completely close or open the gates). The size of governor required for a given size of wheel depends so largely upon the type of gate, head, etc., that no general rules can be given here.

Specifications for Governor. — The following is taken from the standard specifications of one of the large governor manufacturers:

The governors are each guaranteed to develop the energy, expressed in foot pounds stated below, and if not called upon to develop a greater amount of energy than that named, will completely open or close the gates to which they are attached in the following number of seconds:

Type,........Governor,........Foot Pounds,........Seconds,.......

Said governors are further guaranteed: (*a*) to stand substantially steady when the speed does not vary; (*b*) to be dead beat in action and not to hunt; (*c*) to correct with maximum promptness for all load changes within the capacity of the water wheels to which they are attached; (*d*) to maintain the speed steady within half of one per cent under uniform load upon the water wheels to which they are attached; (*e*) to begin to adjust the water-wheel gates when the speed has varied half of one per cent; (*f*) after sudden decrease of load to bring the speed back to normal in...... seconds; (*g*) to operate perfectly in parallel with other governors of the same make.

Dimensions, Weight and Cost of Governors. — On account of the very great variation in the design of governors, it is only possible to give some approximate dimensions and costs which are subject to very large variations for special machines. The following figures pertain to a few standard hydraulic governors.

HYDRAULIC GOVERNORS

Capacity, foot-pounds per stroke	Horse-power of turbine*	Floor space, square feet	Extreme height, feet and inches	Shipping weight, pounds	Cost,* F.O.B. factory
			Ft. In.		
2,500	10 to 400	13	4 11	2,400	$350
10,000	1000	22	7 3	3,700	650 to 1150
30,000	....	30	6 5	6,200	1800
60,000	5000	43	6 7	17,030	2800

* The design of the turbine gates regulates necessary capacity of governor. For the same capacity of governor the cost increases with the speed of the stroke.

LONG PENSTOCKS AND AUXILIARY DEVICES. — When the power required from a wheel varies, the velocity of the water in the penstock must be changed. If the velocity be increased, no trouble will ensue, unless it be increased so rapidly that the water column breaks. If this happens the reuniting of the parts of the water column will prove disastrous. The sudden checking of the velocity of the water may result in very large pressures, which throw severe strains upon the penstocks and wheel cases and may even rupture them.

Calculation of Speed Regulation at End of Long Penstock. — To compute the speed regulation obtainable at the end of a long pipe line proceed as follows: Find the excess energy, above the load requirements, passing through the water wheel gates while they are being closed by the governor in a definite time interval T. This excess energy will be due (1) to the extra water flowing during the time interval T, plus (2) the portion of the kinetic energy of the water column suddenly released by changing the velocity of the stream, minus (3) the energy absorbed in the standpipe, surge tank or other pressure-regulating device. Most of this excess energy will be added to the kinetic energy of the revolving parts, and the final speed will be such as to represent the initial kinetic energy of the revolving parts plus the added energy received during the time of closure. For small increments of energy the per cent increase in speed will be approximately one-half as great as the per cent increase in kinetic energy. There are so many variable factors, namely, length of pipe line, total effective head, velocity of flow, permissible rise in pressure, minimum time of governor action, flywheel effect per horse-power and speed, that it is not feasible to give a general equation for all cases. Each problem must be worked out by itself with the assistance of the water-wheel builder, the manufacturer of the generator, and the builder of the governor.

Water Hammer in Long Penstock. — The following formula, developed by A. H. Gibson of Manchester University (*Water Hammer in Hydraulic Pipe Lines*, London, 1908, p. 12) gives the water-hammer pressure (i.e., the rise in pressure due to closing the gates) under working conditions where there is no standpipe or other relief device.

$$p' = \frac{w}{g}\left[\left(\frac{la'}{aT}\right)^2 + \frac{la'}{aT}\sqrt{2\,gh + \left(\frac{la'}{aT}\right)^2}\right],$$

Where p' = water-hammer pressure in lb. per sq. ft.,
w = weight of one cu. ft. of water (62.4 lb.),
g = acceleration of gravity (32.2 ft. per sec. per sec.),
l = length of pipe line in feet,
a = cross-sectional area of pipe line in sq. ft.,
a' = cross-sectional area of turbine gate in sq. ft.,
T = time in seconds to close gate at a uniform rate,
h = static head in feet.

To obtain the pressure indicated by the formula it is not necessary that the gate be completely closed; closing it partially at such a rate that T is the time which it would require to completely close it gives the same rise in pressure.

Effect of Elasticity of Water and Pipe. — In the case of extremely high head plants the amount of energy which may be absorbed by the compression of the water and the expansion of the pipe near the lower end should be taken into account in computing variations of pressure due to sudden velocity changes. Under certain conditions the elasticity of the water is sufficient to absorb all the kinetic energy even if the water column be very long and stopped very suddenly without causing a dangerously great rise in pressure compared to the normal pressure. This is only true where the normal pressure is very great.

Standpipes. — Under favorable conditions a standpipe may be used to equalize the pressure fluctuations. A standpipe is a vertical pipe in which the water stands normally at the same level as in the reservoir. If the standpipe has an overflow, increase in pressure beyond a certain point can be prevented, but there remains an effect upon the speed regulation due to the diminution of pressure which follows a sudden opening of the gates. At such times the water in the standpipe will fall, while the water column as a whole is accelerating. This temporary fall in pressure will be less the greater the area of

the cross-section of the standpipe near the normal water level. If the standpipe has a very large cross-section the changes in gate opening caused by the governor will not seriously disturb the pressure at the turbine. The diameter of the standpipe may be a matter of relative costs. It does not pay to spend money on closer regulation than the character of the service requires.

For low head developments where long pipe lines are necessary, open gravity standpipes of liberal dimensions, preferably enlarged at the upper end, so as to contain enough water to operate the turbines for several seconds while the main water column is being accelerated, are preferable to other forms of pressure-equalizing devices, from the standpoints of both efficiency and economy. For pipe lines several miles in length it is desirable to provide equalizing reservoirs at intervals along the pipe line, so that the changes in velocity of the water column will be as gradual as possible. If such equalizing reservoirs are not provided it will probably be necessary to arrange the governing mechanism so that the velocity of the water will be increased or decreased very gradually, speed regulation being effected by diverting a portion of the issuing stream, either by a deflecting nozzle, a movable shield, an auxiliary nozzle, or very slow closing by-pass valves.

Calculation of Rise of Water in Standpipe. — The maximum possible rise of water in a standpipe may be determined by computing the total kinetic energy in the moving water column and assuming that it is wholly utilized in raising the water level in the standpipe, which is the assumption equivalent to assuming that the water-wheel gates are closed instantly. Let

A = area of standpipe at and above the normal water level in sq. ft.,
a = area of penstock, assumed to have uniform cross-section in sq. ft.,
l = length of penstock in ft.,
V = velocity of water column in ft. per sec.,
g = acceleration due to gravity = 32.16 ft. per sec. per sec.

Then the momentary rise of water in the standpipe, in feet, upon the instantaneous closure of the turbine gate, is

$$H = V\sqrt{\frac{al}{Ag}}.$$

This formula takes no account of the loss of energy due to friction of water in the water column or standpipe, nor of the absorption of energy in compressing the water, the last of which is regained when the water expands; the error involved in neglecting these losses is small.

Surge Tanks. — A surge tank is a closed tank containing air under pressure and communicating with the penstock. A sudden increase in pressure in the penstock will force the water into the surge tank and compress the air, thus transferring the energy of the water to the air. A decrease in pressure in the penstock will permit the air in the surge tank to expand, returning its energy to the water. Some form of throttling valve or equivalent device must be used between the penstock and the surge tank to dampen the pressure waves which may otherwise become periodic.

Relief Valves. — These are valves similar in purpose to the safety valves on a steam boiler. They allow excess pressure to escape but do not restore energy when the pressure drops. In order to prevent the setting up of pressure waves the relief valves must be so constructed that they will close very slowly after they have opened.

There are many types of relief valves, some depending altogether on the pressure in the water column itself, and others being opened by the same movement of the governor which closes the gates. The latter class of valves

are, on the whole, preferable because they provide a passage through which the surplus kinetic energy of the water column may be discharged without waiting for a rise in pressure. These governor-actuated valves are generally designed to close slowly after the initial opening movement.

By-pass Valves. — By-pass valves may be utilized to maintain constant velocity of the water in the pipe line by opening the by-pass the same amount as the passageway though the water-wheel gate is closed and vice versa. Such valves are very wasteful of water, but their use is justified in certain cases where the stream is utilized for irrigating purposes. Deflecting nozzles used for impulse wheels belong to this class of devices. To conserve water the by-pass may be arranged so as to close gradually after it has opened. This closing should be so gradual that no water hammer is produced in the penstock.

Deflecting Nozzles. — When impulse wheels are used, the regulation is commonly effected by suddenly diverting the stream issuing from the nozzle so that a less or greater portion of the stream strikes the wheel. Such devices are preferably arranged so that when the deflection of the nozzle becomes greater than a certain predetermined amount, the cross section of the stream through the nozzle is slowly varied by the axial movement of a needle valve inside the nozzle. This is best accomplished by electrical contacts which are touched by some part of the nozzle when it is deflected more than a certain amount from the normal. These contacts permit current to flow to a small motor which actuates the needle valve.

BIBLIOGRAPHY. — A complete bibliography up to 1908 is given in Mead's *Water Power Engineering*. Some recent books and articles dealing with speed regulation of water wheels are: Koester, F., *Hydroelectric Developments and Engineering*, N. Y., 1909; Von Schon, H. A. E. C., *Hydro-Electric Practice*, Phila., 1908; *Speed Regulation in Hydro-Electric Plants*, A.S.M.E., Feb., 1911; *Oil Pressure Governor for Water Wheels*, Elec. World, Jan. 6 and Feb. 17, 1912.

[L. E. Moore.]

WATTHOUR METERS. — (*See also Amperehour Meters; Electrodynamometers; Wattmeters.*) A watthour meter consists essentially of (1) a small electric motor, which may be either of the commutator type, mercury and disc type, or induction type, (2) a brake system composed of a disc of non-magnetic material (usually copper or aluminum) mounted on the armature spindle and so arranged that its edge rotates between the poles of one or more permanent magnets, and (3) a system of gears with numbered dials forming a suitable registering mechanism for indicating the number of revolutions of the armature or disc. One winding, called the "potential" coil, is connected across* (in shunt with) the load and the other winding, called the "current" coil, is connected in series with the load, the connections being the same as for an indicating wattmeter; see *Wattmeters.*

Principle of Operation. — Motor-type meters are so constructed that the average torque exerted by the motor is proportional to the average power taken by the load. The brake system is so designed that the opposing torque, due to the eddy or Foucault currents induced in the disc as it rotates between the poles of the permanent magnets, is proportional to the speed of the disc. When the disc acquires a given speed the driving torque must be just equal to the opposing torque, and must therefore be proportional to the speed. Hence the speed of the disc is proportional to the average power, and therefore the total number of revolutions which the disc makes during any interval must be proportional to the total energy input during this interval, whether the power remains constant or varies. To determine the energy input to the load in watt-hours or kilowatt-hours it is therefore only necessary to take the difference between the dial readings at the beginning and end of the given interval, and multiply by the proper constant if the meter is not direct reading.

Sources of Error. — In a d-c. watthour meter the chief source of error is the friction of the brushes (which is more or less variable), friction of the bearings of the motor and gear train, and air friction, the brush friction being by far the most important. In a-c. watthour meters, the lack of exact 90° phase relation between the impressed voltage and the magnetic flux due to the current in the potential coil may cause additional errors which vary with the frequency, power factor and also with the distortion of the wave form; in modern meters these errors are practically negligible. Instrument transformers (*see Transformers, Instrument*), unless properly designed, introduce additional sources of error. Devices and methods for overcoming, or of correcting for, these errors are described below.

Classification according to Service. — Watthour meters may be classified according to the service in which they are used, viz., (1) house meters for use in residences or factories, (2) switchboard meters for use in central stations, and (3) meters for use in individual power installations and isolated plants. Meters for house service are generally front-connected, separately-sealed devices which can be installed and sealed to prevent tampering. Switchboard meters are generally back connected and of such design as to match other switchboard devices. "Meter-boards," equipped with the necessary auxiliary or protective devices, are frequently used with house meters, in order to insure proper connections and sealing.

COMMUTATOR TYPE OF WATTHOUR METER. — The commutator type of meter is now used only on direct-current circuits, although before the induction meter was so highly perfected large numbers were used for alter-

* Either directly or through suitable instrument transformers; see *Transformers, Instrument.*

nating current as well as for direct current. The motor consists of a set of stationary coils, commonly called field coils, which carry the current, and an armature wound with small wire which is connected across the terminals of the load or in shunt with the supply circuit; generally a series resistance is used to absorb part of the line voltage. The connection to the armature is by a commutator and brushes, as in an ordinary commutator type of shunt motor. Special attachments are sometimes added for very large capacities, such as double armatures astatically arranged, and damping magnets inclosed in a laminated iron shield in order to reduce stray-field errors where heavy currents are used and heavy short-circuits are frequent.

It should be noted that the operation differs from that of an ordinary shunt motor in that the speed increases with increase of field strength, since its back e.m.f. is much less than 50 per cent of the line voltage.

On account of the inductance of the windings of the commutator meter, it does not record accurately on a-c. circuits unless properly compensated, the error being greater the less the power factor.

Compensation for Friction; Light-load Adjustment.—Friction in a well-designed watthour meter will be very small and will be noticeable only on light loads of 10 per cent and below. To compensate for this friction, a "light-load adjusting coil" is added, which is an auxiliary or compounding coil. This light-load coil is connected in series with the armature. It is placed adjacent to the field coils so that its field strengthens the main field and produces a slight torque independent of the power and just sufficient to compensate for friction.

Details of Construction, Bearings, etc. — In the design of the modern direct-current commutator type of watthour meter, great thought has been given to the mechanical construction in order to obtain small air gaps between the armature and field coils, light-weight armatures and commutators and brushes which will have very small friction and yet stand the wear and carry the current to the armature without undue sparking and pitting of the contact parts. In a watthour meter of the most approved design the field coils are wound with enameled copper strips and the armature winding is enamel-covered wire wound on a paper sphere mounted on a spindle of light steel tubing. The lower bearing carries all of the weight and the upper bearing is a guide bearing, as all meters have vertical shafts. The lower bearing consists of a steel pivot mounted in the end of the spindle or armature shaft, running on a jewel bearing. In most cases a good grade of sapphire is used for the jewel and is cupped and polished so as to provide a bearing with as little friction as possible. Of late years a great deal of attention has been given to the bearings and in some cases, particularly on high-capacity meters with astatic armatures and a correspondingly heavy weight, diamond jewels are being used with excellent results. The diamond jewel will last much longer than the sapphire before wearing sufficiently to increase the friction and thereby change the accuracy of the meter, particularly at light loads. See also section below on *Data on House-Type Meters*.

Capacity of Commutator Watthour Meters. — Commutator-type direct-current meters are built in capacities ranging from 5 to 10,000 amperes, 100 to 600 volts. Meters of this type are furnished with double-current circuits for three-wire circuits, the maximum ampere capacity for three-wire meters being about 6000 amperes. Special meters have been supplied for 1200- and 2400-volt railway circuits.

Accuracy. — Tests on direct-current commutator meters show that a meter of good design should start on two per cent of full load and should give accuracies about as follows: — To within 3½ per cent from 5 per cent to ¼ load,

2 per cent from ¼ to full load. The Public Service Commission of New York State allow no d-c. watthour meters to be used which are not accurate within the following limits:

Per cent rated current.....	5	10	20	50	100	150
Maximum deviation, per cent.	7.5	3.0	2.0	2.0	2.0	2.0

MERCURY-MOTOR WATTHOUR METER. — The mercury-motor watthour meter has been manufactured for both alternating and direct current, but at the present time its use is practically limited to direct current, as the induction type of meter has been found superior for alternating current. The motor element consists of a mercury well or reservoir in which is partially floated a metal armature disc or drum, usually of copper. The chamber is filled with mercury and fitted with a non-spillable opening at the top through which the spindle is attached. The main current is led into the mercury by means of electrodes, and since mercury has about forty times the resistance of copper the major part of the current traverses the armature disc or drum, passing out through the mercury to the opposite electrode. The potential or shunt coil is wound with many turns and is mounted on a laminated iron core so placed that the flux set up will cut the armature disc or drum.

The torque exerted on the disc or drum is proportional to the product of the current through the disc and the current in the potential coil, and therefore to the power supplied to the load. A brake system similar to that used in the commutator type of watthour meter renders the speed proportional to the torque and therefore to the power supplied to the load.

Compensation for Friction, Light-load Adjustment. — For compounding or light-load compensation for friction, a thermal device is used in some cases, and it is also possible to obtain compensation by shunting part of the potential circuit through the armature disc. The thermal device employed is a thermocouple shunted around the mercury chamber, and heated from a resistance coil connected across the line. The small current generated in the thermal couple forces a slight current through the armature and produces a compounding effect.

Application of Mercury Meters. — Mercury-motor meters, on account of the low resistance of the current circuit (disc or drum), are particularly well adapted for use with external shunts, since but a small potential drop in the shunt is required. They are therefore used in comparatively large numbers for switchboard work where large currents are used and where external shunts can be conveniently installed.

Details of Construction. — The several designs of mercury-motor meters on the market differ in mechanical construction and in methods for obtaining light-load adjustments. The chief difference in mechanical construction is in the motor element, where a mercury chamber of non-metallic compound is used in some cases, and a german silver chamber enameled on the inside in other designs. Armatures differ in that some designs use a copper disc and others a copper drum or thimble. See also section below on *Data on House-Type Meters*.

Capacity of Mercury Watthour Meters. — Direct-current mercury meters are in themselves independent of ampere capacity, as external shunts are used. Shunts giving a capacity as high as 60,000 amperes have been furnished. Meters designed for voltages up to 600 volts can be furnished without any difficulty and special meters have been supplied for 1200- and 2400-volt direct-current railway circuits.

Accuracy. — The light-load accuracy of a mercury-motor meter may vary on account of varying friction of the armature disc in the mercury, and

there is an overload droop in the accuracy curve due probably to heating of the mercury and a slight buckling of the armature disc by the current; see Fig. 1. The mercury meter also shows hysteresis errors due to the fact that iron is used in the potential circuit. For this reason the meter shows a small

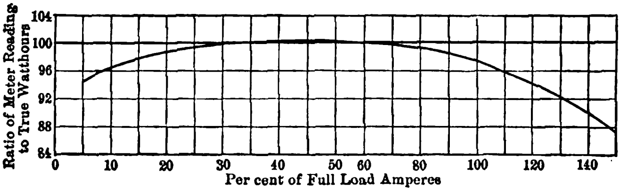

Fig. 1. Calibration Curve of Mercury Motor Meter

difference in reading when the voltage is raised and then lowered even though through a comparatively small range. Direct-current mercury-motor meters for house service should have an accuracy within the limits given above, for commutator meters.

INDUCTION WATTHOUR METER (Fig. 2).—This type of meter, the essential elements of which are illustrated in Fig. 2, has a laminated soft-iron core on which is mounted the current and potential windings. The current winding consists of a few turns of coarse wire, while the potential coil has many turns of fine wire. The flux due to the current coil is in phase with the load current, and the flux due to the potential coil is approximately in quadrature with the voltage across the load, since the potential coil is highly inductive; see *Alternating Currents*. The poles from the two windings are arranged so that the armature disc passes between them and is cut by the alternating flux due to each winding.

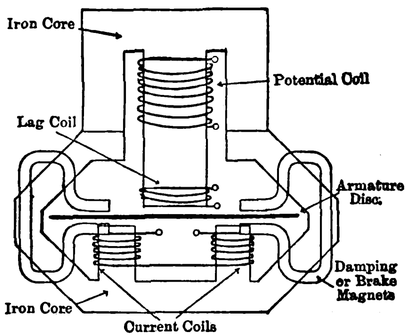

Fig. 2. Diagram of Induction Watthour Meter

Principle of Operation. — There is thus set up in the disc currents which flow about each pole in approximately concentric circles, the induced currents due to the two windings being in quadrature for a load of unity power factor (approximately only, unless a suitable phase compensator is used; see below). Part of the current induced by the current coil passes under the pole of the potential coil and therefore through a magnetic field which is approximately in phase with this current, and similarly part of the current induced by the potential coil passes under the pole of the current coil and therefore through a magnetic field approximately in phase with it; for power factors less than unity the phase difference between these currents and the magnetic fields through which they pass is the same as the difference in phase between the load current and voltage. Hence a torque is produced on the disc having an average value proportional to the load supplied through the meter; see *Electricity and Magnetism*,

Principles of. A braking system similar to that employed in the commutator type of meter (see above) causes the speed of the disc to be proportional to this average torque, and therefore the number of revolutions is proportional to the energy supplied.

Phase Compensation; Lag Coil. — In order to make the induction watthour meter record correctly, especially for power factors less than unity, it is necessary to cause the current in the potential coil to lag *exactly* 90 degrees behind the current in the current coils. A common method of securing this condition is to mount on the potential pole a short-circuited winding the resistance of which can be varied by a resistance wire soldered to the terminals.

Compensation for Friction; Starting Plate. — The light-load adjustment can be obtained by placing a short-circuited loop of copper adjacent to the potential pole so that it can be shifted in a plane at right angles to the axis of the potential coil. This loop has induced in it currents which produce a field out of phase with the flux from the potential coil, and the reaction between these two produces on the disc a slight turning moment independent of the current in the current coil. The amount of compensation can be varied by shifting the position of the light-load coil, or starting plate, as it is sometimes called.

Details of Construction. — The induction type of watthour meter is manufactured in several different types all based on the same principle of operation but differing in mechanical construction and electrical characteristics. The general type of construction is to mount the iron core and windings on a metal frame, which carries the bearings for the armature, the core and windings being combined as a single unit in some designs, whereas in others the current and potential coils with their iron cores are mounted separately on a common frame or on the meter case. The other details of design consist of mounting the registering train and damping magnets and arranging the full-load, light-load and power-factor adjustments so that they are readily accessible. See also section below on *Data on House-Type Meters*.

Polyphase Induction Meters. — The polyphase induction meter in commercial use is nothing more than two single-phase meters with a common spindle connecting the two armature discs. The measurement of power with the meter is based on the two-wattmeter method for three-wire, three-phase and quarter-phase work (*see Wattmeters*), and a slight modification of the two-element meter is used quite extensively for four-wire, three-phase work. The modification consists of making a third current circuit by adding a winding to the current coils of both elements. Such a construction is quite accurate except on badly unbalanced voltages, the most accurate arrangement for such work being three separate single-phase meters, or a single meter which contains three single-phase elements.

Capacity of Induction Watthour Meters. — Induction type meters are supplied in standard capacities ranging from 5 to 300 amperes both two- and three-wire single-phase and up to 150 amperes polyphase. Meters are generally used with self-contained potential circuits up to 600 volts, and for higher voltages and current capacities potential and current transformers are used with 5-ampere, 110-volt meters. When transformers are used, either a multiplying constant for the dial alone can be used in connection with the ratio of transformation of the transformers, or the ratio of the transformer can be included in the meter constant (see below), so that the register is direct reading with the transformers of proper ratio. For three-wire, single-phase circuits it is possible to obtain a special form of current transformer with double primary windings and a single secondary winding for connection to the meter.

Accuracy. — Modern induction watthour meters are susceptible of a higher degree of accuracy than the commutator or mercury-motor meter. Fig. 3 shows

a typical characteristic curve of an induction watthour meter. It is possible to obtain by special calibrations a combination of induction watthour meters and

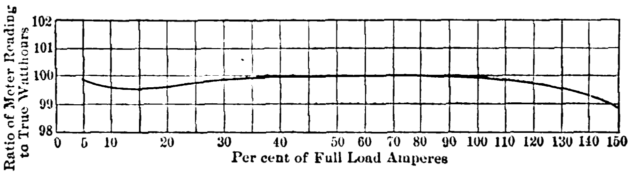

Fig. 3. Calibration Curve of Induction Watthour Meter

instrument transformers which will be accurate to within 1 per cent over the ordinary range of commercial operation.

The requirements of the New York Public Service Commission, Second District, are cited as showing accuracies which are necessary and which are met by the modern meter of the induction type:

Per cent rated current....	5	10	20	50	100	150
Maximum deviation......	3.0	1.5	2.0	2.0	1.5	3.0

The characteristic curve usually crosses the 100 per cent line at about 10 per cent and 100 per cent load; the meter can therefore be held to closer limits at these points. Meters must also be adjusted for measurement on power factors of 75 per cent and 50 per cent to within 2 per cent and 4 per cent respectively. Other requirements of accuracy can be found in the rules and regulations governing watthour meters issued by Public Service Commissions.

PREPAYMENT METERS. — Standard watthour meters are sometimes fitted with a device whereby the circuit through the meter and load is closed only upon the insertion of a coin into the device, and remains closed only until a certain predetermined amount of energy has been recorded by the meter, when the circuit again opens automatically. When so equipped the meter is called a prepayment meter. The prepayment device may be either inserted in the watthour meter, or it may be placed in a separate attachment electrically connected to the meter.

OTHER TYPES OF WATTHOUR METERS. — The descriptions of watthour meters given above refer particularly to the types manufactured in the United States. Meters of the same general types are manufactured abroad, as well as certain other types. Among the latter, the Aron clock meter is worthy of notice. In this meter the potential coils are carried on two pendulums arranged in such a manner that they swing close to the coils carrying the line current. One pendulum must be retarded as the other is accelerated and to do this connections are so made that the instantaneous polarity of the pendulum coils is always opposite while the current coils are always alike. The meter contains no iron and has no commutator and is, therefore, a very accurate measuring device, although somewhat complicated and delicate of adjustment for ordinary commercial work.

DATA ON HOUSE-TYPE METERS. — General data on house-type watthour meters of different types is tabulated below. These data are approximate, but are representative of modern practice in this country.

COMMERCIAL SINGLE-PHASE HOUSE-TYPE METERS

Item	Commutator type	Mercury type*	Induction type
Total weight, pounds	14 to 15	10 to 15	8 to 10
Height, inches	12	6.5	6
Width, inches	7.5	7	7
Depth, inches	6.5	4	4.5
Torque of motor element at full load, gram-millimeters	170	20 to 30	30 to 70
Weight of armature, grams	100	60 to 70†	11 to 30
Watts lost in potential circuit at 110 volts	5	5	1 to 3
Watts lost in current circuit at full load	5.5	1‡	0.5 to 1.5
Resistance of potential circuit, ohms	2100	....	....
Drop across shunt, millivolts	....	60 to 100	....

* The data on the mercury type also apply to meters used with shunt of any capacity.
† Partially supported by mercury. ‡ Not including shunt.

TESTING OF WATTHOUR METERS. — For laboratory tests the meter should be mounted on a firm support and set level. These conditions should also obtain when the meter is permanently mounted for service; see below under *Installation*. For laboratory tests a bank of lamps or some form of rheostat may be used for a load. The instructions given below apply to both laboratory and service tests.

Testing Instruments. — For d-c. measurements a portable ammeter and voltmeter or a standard watthour test meter may be used; for a-c. measurements an indicating wattmeter or standard watthour test meter may be used. Two instruments of different capacities should be provided, one of sufficient capacity to take care of the full load of the meter and the other of small enough capacity to read the light load with a proper degree of accuracy.

The use of a portable watthour test meter is now recognized as the standard method for testing watthour meters up to 100-ampere capacity. There is no question as regards the accuracy of this method, since it is not necessary that the load be constant. With the portable test meter, indicating instruments and stop watches are unnecessary, and personal errors in reading are thereby reduced.

When indicating instruments are employed, a reliable stop watch is essential for taking the meter speed. As a matter of safety, it is advisable to have at least two stop watches, one to serve as a check on the other in test. Too much care cannot be used in the handling of these watches and in giving them careful checks with some local jeweler's standards. In checking the stop watch it is advisable to check at different points of the dial.

Precautions. — In order to insure accuracy, d-c. meters should not be tested until they have been connected in circuit and the current on for fully 15 to 20 minutes before the test is made. This enables the heating effect of the current in the potential circuit to become constant. If the meters are tested before this consecutive readings may not check.

The testing instruments should not be allowed to measure the losses of the potential circuit of the meter under test, or vice versa. In order to avoid this the current circuits of the testing instrument should be connected in series with the meter under test, while the potential circuits of the testing instrument and of the meter under test must both be connected across the line at the same place and between the generator and the nearer instrument.

A number of revolutions should be taken so that the time of observation will be at least from 40 to 60 seconds. If the time is materially less than 40 seconds, errors in the measurement of time are probable; a time interval longer than 120 seconds is generally unnecessary.

Meter Constant. — In checking a watthour meter the speed of the disc is timed directly, since too long a time would be required to obtain a suitable reading on the dial of the instrument. The relation between the number of revolutions of the disc and the corresponding dial reading may be expressed by a constant multiplier, called the "meter constant," which depends only upon the gearing between the disc and dial. Various manufacturers express this constant differently, viz:

G. E. Meter Constant (K). — The number of watthours indicated by the register per revolution of disc; its value is marked on the disc.

Westinghouse Meter Constant (K). — Meters of Westinghouse manufacture are all adjusted for a certain speed at full load or rated capacity, which is stamped on the nameplate. Meters of modern manufacture have a speed of 25 r.p.m., and older forms of 50 r.p.m. Let N be the number of revolutions per minute corresponding to a rating of P kilowatts, then the meter constant K (the number of watt-seconds per revolution of disc), as given in the instruction books issued by this company, is $K = \frac{60{,}000\,P}{N}$.

Fort Wayne Meter Constant (C). — For type K meters the number of watthours for 36 revolutions of the disc; for types K_1, K_2, K_3 and K_4 the number of watthours for 1 revolution of the disc; the constant is marked on the disc.

Duncan Meter Constant (K). — The number of watthours per revolution of the disc; it is marked on the disc.

Sangamo Meter Constant (K). — The number of watt-seconds per revolution of disc; it is marked on the register in the mercury-motor meters and on the disc of the induction meters.

Calibration Formulas. — Let R = number of revolutions of disc, S or T = number of seconds for R revolutions, K or C = meter constant as defined above: Then the corresponding reading of the meter in watts is:

Type of meter	Meter reading in watts
G. E.	$\frac{3600\,KR}{S}$
Westinghouse	$\frac{KR}{T}$
Fort Wayne, Type K	$\frac{100\,CR}{S}$
Fort Wayne, Types K_1, K_2, K_3 and K_4	$\frac{3600\,CR}{S}$
Duncan	$\frac{3600\,KR}{S}$
Sangamo	$\frac{KR}{S}$

Per Cent Accuracy. — The meter reading as thus calculated divided by the true watts, as read on the test meter, and multiplied by 100, gives the per cent accuracy. If the per cent accuracy is less than 100 the meter is running slow; if greater than 100 it is running fast.

Adjusting Speed of Meter. — If the error in the meter reading at full load is in excess of the permissible error the speed should be altered by adjusting the position of the permanent magnets or shunting part of their flux by the means provided therefor. If the error at light load, say 5 per cent load, is excessive, the light-load adjustment should be altered to bring the speed to its correct value.

Method of Using the Portable Watthour Test Meter. — The dial of the test meter reads directly in revolutions of the meter disc. At the instant the mark on the disc of the service meter passes some arbitrarily chosen fixed point, note the dial reading of the test meter. Count the number of revolutions of the disc of the service meter, and at the instant when a suitable whole number of revolutions are completed note the dial reading of the test meter again. Let R_0 be the difference in the two dial readings of the test meter, K_0 the meter constant of the test meter, R the number of revolutions of the service meter and K its meter constant. Then the per cent accuracy is $\frac{KR}{K_0R_0}$. Of course the meter constants of the two meters must be expressed in the same manner, i.e., as watt-hours per revolution or as watt-seconds per revolution.

Testing of Three-wire and Polyphase Meters. — A three-wire meter can be tested as a two-wire meter by connecting the current coils in series. The three-wire meter will then read twice the number of watts actually supplied to the test load. By using two sets of instruments three-wire meters may be tested as actually used.

A polyphase meter is most readily tested as a single-phase meter with the current circuits in series and the potential circuits in parallel. The reading of the meter is then twice the number of watts actually supplied to the test load.

INSTALLATION OF WATTHOUR METERS. — A watthour meter should always be mounted on a firm support, should be set level, and in a place where it will not be liable to be injured or subjected to weather. A firm support is particularly essential, as continual vibration of the meter may cause it to "creep," since vibration tends to lessen the friction, and the friction compensation may then be excessive.

Meters should not be installed closer than about fifteen inches between centers, and should not be too close to conductors carrying heavy currents or in the vicinity of iron girders, posts, water or steam pipes.

A check on its accuracy should always be made after the installation of a meter.

Determination of the Capacity of Meter. — Before installing a meter some tests or accurate estimates should be made to determine the correct capacity of meter to install, as it is not advisable to run a meter continuously above its rated capacity, and too large a capacity of meter means in general poor accuracy on account of running it at light load. As a rough guide, the capacity of the meter should be one-half the combined capacity of the total connected load for ordinary residences, three-fourths the total connected load for stores and offices, and 1½ times the connected load for elevator, hoist and other motors taking a large starting current.

Precautions in Connecting Polyphase Meters. — Direct-current and single-phase alternating-current meters are comparatively simple to install and connect properly, but all installations on polyphase circuits require considerably more care and knowledge to insure proper connections. Polyphase induction meters must be connected properly in regard to phase relations, as otherwise very inaccu-

rate results will be obtained, which may not be apparent on casual examination of the meter. The manufacturers instructions should be followed very carefully and the phase relations traced out to make sure that they are correct. Practically all instrument transformers are now marked in some distinctive manner to indicate the relative instantaneous polarity of the primary and secondary windings, in order to facilitate making connections.

MAINTENANCE, REPAIRS AND DEPRECIATION. — It has been found from experience that except for the very smallest central stations or distributing companies that it is economy to maintain some systematic method of testing and caring for all meters on the system. For ordinary house service and all except very large installations, readings are taken about once a month and meters are examined and tested about once a year. Commutator-type and mercury-motor meters should undoubtedly be tested and put in good condition at least once a year; induction meters may be left for two years and perhaps more before examination, as the very slight change in accuracy is not enough to warrant the expense of the test. With very large capacity meters, where the amount of money involved is large, frequent tests are made and in some cases a monthly check and adjustment is made, and whenever necessary the meter is given a complete overhauling and a spare meter installed in the meantime.

Repairs. — In making repairs on watthour meters, it is practically necessary to maintain considerable equipment and a department for this class of work. Unless such a department is available it is preferable to return meters to the manufacturer for all repairs except those of a minor nature, such as cleaning of commutators on direct-current meters and inserting new jewels and pivots for the lower bearing. Manufacturers will usually supply repair parts at reasonable prices and quite extensive repairs can be made by the central stations if they are properly equipped. In service the attention and care necessary vary with the type of meter, induction meters being by far the cheapest to repair and under most conditions such meters require the least attention of any type.

Cost of Watthour Meters. — The ordinary house type of commutator type meters for direct-current service range in price from $12.00 to $100.00. Large-capacity switchboard commutator meters in capacities from 1000 to 10,000 amperes are sold at prices ranging from $100.00 to $500.00.

Mercury-motor meters usually have external shunts and the meter itself is of about 10 ampere capacity and sells for about $10.00 in the house type and for about $50.00 to $60.00 in the switchboard type. Prices of shunts for these meters vary, being roughly $2.00 for a 100-ampere, $20.00 for a 500-ampere, $30.00 for a 1000-ampere and $50.00 for a 5000-ampere meter.

At the present time small-capacity single-phase induction meters for house service are sold for about $7.00 to $10.00 each; larger capacities and polyphase meters vary in price from $30.00 to $50.00. The commercial forms of switchboard induction meters of large capacity sell for about $40.00 to $75.00; they are 5-ampere meters designed for use with instrument transformers, q.v.

Besides the original expense of the cost of the meter itself, there is the cost of installation and necessary attachments to mount and connect the meter. In most cases, except for very large installations, the expense of the meter itself is a small part of the total installation cost. It has been estimated that the installation cost of an ordinary house meter is about $5 or $6, not including the cost of the meter itself.

G., *Electricity Meters*, London, 1906; Shepard and Jones, *The Watthour Meter*, San Francisco, 1910; Ziegenberg, R., *Der Elektrizitätszähler*, Berlin, 1912. [L. T. ROBINSON.]

WATTMETERS. — (*See also Ammeters; Braun Tube; Electrodynamometers; Electrometers; Voltmeters; Watthour Meters.*) A wattmeter is a device for measuring electric power and is particularly useful for measuring alternating-current power. Usually some form of electrodynamometer is used in which the current in the circuit or a known part of it is sent through one winding, the current coil; and a small current in phase with the e.m.f. across the terminals of the circuit is sent through the other winding, or potential coil; see Figs. 1 and 2. The small current in the potential circuit is drawn through a resistance as in a voltmeter. For voltages above 150 to 750 volts, potential transformers (*see Transformers, Instrument*) are usually employed. In some cases specially-constructed resistances, or multipliers, are employed in testing work up to 25,000 volts or even higher. The moving coil is generally used for the potential circuit as it is more convenient to carry through it a small current than a large one.

Principle of Operation. — In an instrument constructed and used as above described, the current in the current coil is practically proportional to the load current i at each instant and the current in the potential coil is practically proportional to the voltage v across the load at that instant. Hence the instantaneous torque acting on the moving element at this instant is proportional to vi or to the instantaneous power. The average torque acting on the moving element during each cycle of the current and voltage is then proportional to the average power. If the free period of the moving system is large compared with the period of the current and voltage, then the steady reading will also be proportional to the average power.

CONSTRUCTION OF WATTMETERS. — The electrodynamometer type of instrument is built in several forms, e.g., the original Siemens electrodynamometer in various forms in which the moving coil is brought back to zero by means of a torsion head from which the reading is obtained; deflection instruments in which the moving coil is allowed to advance through an angle until the force exerted on it by the currents in the instrument windings is balanced by the restoring torque developed in a spring or equivalent device. In the latter form of instrument the position of the moving coil is usually read by means of an attached pointer passing over a scale, graduated to read directly in watts or decimal multiples. In very sensitive instruments for laboratory use a beam of light or a telescope and scale like those used with mirror galvanometers is employed; see also *Electrodynamometers.*

In addition to the electrodynamometer type of instrument, induction wattmeters, operating on the same general principle as the induction watthour meter (*see Watthour Meters*), are sometimes used for switchboard and even for portable work, but they are not so generally useful through wide ranges of frequency and voltage as electrodynamometer instruments.

For certain limited conditions electrostatic wattmeters (*see Electrometers*) have been successfully used; in this general class of wattmeters for special purposes may be included the cathode-ray oscillograph or Braun tube (*see Braun Tube*).

Polyphase wattmeters, having two or more sets of current and potential windings contributing torque to a common shaft, are made for use on polyphase circuits; see below under *Measurement of Three-phase Power.*

Range of Different Types of Wattmeters. — Reflecting electrodynamometer wattmeters for laboratory use are made for currents up to 100 or 200 amperes and for use on circuits from a fraction of a volt up to 150 volts. Such instruments have been specially constructed for larger currents and higher voltages. See article on *Electrodynamometers.* Such instruments are chiefly useful for measurements on circuits of low voltage and of low power factor where even

the small power required to operate the instrument makes the use of ordinary portable instruments inconvenient or impossible.

Portable wattmeters are usually made to give a full-scale deflection with two-thirds of the product of their rated amperes and volts, i.e., an instrument rated as 5 amperes and 150 volts would usually have a 500-watt scale. For determining core-losses and other service where the power factor is low, instruments may be found giving full-scale reading with one-third or less of the product of the rated amperes and volts. It is customary to supply such wattmeters with a certificate showing the values of the equivalent phase angle α (*see below*) that have been determined, so that they may be used where a high degree of precision is required on low power factor work.

Portable instruments are made in sizes up to 200 amperes and 750 volts. Extra potential terminals are sometimes supplied so that the instruments may be used on more than one voltage, e.g., 125 or 250 volts. On the low power factor instruments this makes it possible to measure the watts with a good scale reading on either low or high power factor, the 250 terminal being used on a 125-volt circuit and the reading multiplied by two. Double-current windings are also supplied with a paralleling switch, thus extending the current range, and in some sizes it is possible to procure double range for volts and current in the same instrument.

Portable instruments for larger currents than 200 amperes and higher voltages than 750 have been successfully constructed but are not generally used, because the higher ranges can usually be taken care of with 5-ampere 150-volt instruments in connection with calibrated instrument transformers.

Switchboard instruments are made single phase up to 200 amperes and 750 volts, and polyphase up to 50 or 100 amperes and up to 750 volts. Higher ranges are usually taken care of by using 5-ampere instruments in connection with instrument transformers.

Switchboard wattmeters are constructed in various sized cases and forms to match other switchboard instruments.

METHODS OF CONNECTING WATTMETER TO LOAD; CORRECTION FOR POWER LOST IN WATTMETER. — A wattmeter may be connected to the load which it is to measure in either of the two ways illustrated in Figs. 1 and 2. When connected as in Fig. 1 the current through the

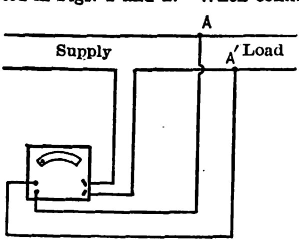

Fig. 1. Includes Loss in Potential Circuit

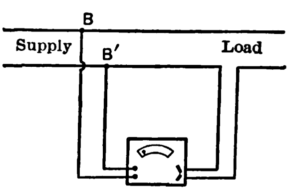

Fig. 2. Includes Loss in Current Coil

current circuit is equal to the sum (vector sum in the case of alternating currents) of the current taken by the load and that taken by the potential circuit of the wattmeter; hence the wattmeter will read the sum of the watts taken by the load and the watts lost in the potential circuit. The loss in the potential circuit is equal to $\frac{E^2}{R_p}$, where R_p is the resistance of the potential circuit and E the voltage across the load. For precise work this correction should always be made, unless the wattmeter is "compensated"; see below.

In the second scheme of connection, Fig. 2, the current through the current circuit is the same as that taken by the load, but the voltage across the potential circuit is higher than the voltage across the load by the voltage drop through the current circuit of the instrument, and the wattmeter reads too high by an amount equal to the watts lost in the current circuit. This loss is equal to R_cI^2, where R_c is the resistance of the current circuit and I the load current. This loss is usually less than the loss in the potential circuit which occurs when the first scheme of connection is used. If no correction is made for the wattmeter loss the scheme of connections shown in Fig. 2 should therefore be used. If the highest precision is required, especially when a small-capacity wattmeter is used, the connections shown in Fig. 1 should be used, and a correction should be applied. The resistance of the potential coil is usually stated on the case of the instrument.

When a voltmeter is connected to the load across AA' in Fig. 1, while the wattmeter reading is being taken, a correction should also be made, if appreciable, for the power taken by the voltmeter. Calling R_v the resistance of the voltmeter and multiplier, if any, and E the voltage across the load, the loss in the voltmeter is $\frac{E^2}{R_v}$. In most cases the potential circuit losses in the wattmeter and voltmeter are best determined by a direct measurement with the wattmeter using the test voltage and leaving the current circuit open. If the voltmeter is connected across BB' in Fig. 2, then the power lost in it is not read by the wattmeter, but the voltmeter reading is not exactly equal to the voltage across the load, but equals the load voltage plus the resistance drop (or impedance drop, added vectorially, in the case of an alternating-current circuit) through the current circuit of the wattmeter.

Compensation for Wattmeter Loss. — In the so-called compensated wattmeters a stationary compensating coil inside the instrument is connected in series with the potential coil, this compensating coil being so placed that the current through it produces on the moving element a torque equal and opposite to that produced by this same current when it passes through the current coil. A compensated wattmeter should always be connected to the circuit, as shown in Fig. 1; when so connected no correction for the loss in the wattmeter is made.

SOURCES OF ERROR. — Due to the unavoidable inductance in the potential circuit of a wattmeter, the current in the moving system is reproduced not exactly in phase with the e.m.f. impressed on the circuit; in addition there are other small inherent defects in wattmeters, such as eddy currents in windings, supports, etc., which tend to make commercial wattmeters more or less imperfect. These imperfections are more serious as the frequency of the circuit is raised and the power factor is lowered.

For precision testing under service conditions when the best obtainable accuracy is required, it is often desirable to apply corrections to wattmeter observations to eliminate the errors due to phase displacement, or its equivalent, in the potential circuit; when instrument transformers are used, additional phase displacement occurs, rendering such corrections especially important. In other cases where corrections cannot well be applied, it is useful to consider the magnitude of the error that will occur under any given conditions, in order to select suitable instruments and transformers and to arrange the loads connected to their secondaries in such a way as to produce as near as may be the desired results. In many cases indications that would otherwise be considerably in error may be made to give results of satisfactory accuracy by correcting for phase displacement in the wattmeter, and particularly in the instrument transformers.

There are many ways in which the necessary corrections may be determined and applied but the following has been found satisfactory in practical work.

Equivalent Phase Angle of Wattmeter. — All the errors in wattmeters may be considered as due to a certain phase displacement between the current in the potential coil and the impressed e.m.f. of the circuit. This equivalent angle of phase displacement may be due to a variety of causes, but can be determined for any given instrument from the following relations. Consider a wattmeter in which the current in the potential circuit lags α degrees behind the e.m.f. impressed on the potential circuit, the meter being in all other respects perfect. If such a meter is used to measure the watts P supplied by a current I at a voltage E, this current lagging behind E by an angle θ, the wattmeter will read $P_2 = EI \cos \theta_2$ watts, where $\theta_2 = \theta - \alpha$. Hence if a wattmeter is used to measure a known load of P watts with I amperes and E volts, and the wattmeter reads P_2 watts, the equivalent phase angle of the wattmeter may be defined by the relation

$$\alpha = \cos^{-1}\left(\frac{P}{EI}\right) - \cos^{-1}\left(\frac{P_2}{EI}\right).$$

This angle α is to be taken positive when the wattmeter reads too high on an inductive load and negative when it reads too low on an inductive load.

For a given wattmeter and given potential coil this equivalent phase angle is practically constant for all currents, voltages and load power factors, provided the frequency remains constant.

In the best portable and reflecting instruments α is usually + and very small. In a portable instrument built for a 125- to 150-volt circuit, when used on a 60-cycle circuit, α may have a value of + 5 minutes or + 6 minutes and possibly as much as + 10 minutes; for higher voltages and lower frequencies α is correspondingly less. For example, in a particular wattmeter this equivalent phase angle equals 3′ for the 125-volt coil and 1.5′ for the 250-volt coil, both at 25 cycles per second, and equals 7′ for the 125-volt coil and 3½′ for the 250-volt coil, both at 60 cycles per second.

Correction for Phase Angle of Wattmeter and of Instrument Transformers. — Let α = the phase angle of the wattmeter, as defined above, β = the phase angle of the current transformer, γ = the phase angle of the potential transformer (*see Transformers, Instrument*), P_2 = wattmeter reading corrected for scale error and multiplied by the product of the corrected ratios of the current and potential transformers, E = voltmeter reading corrected for scale error and multiplied by the ratio of the potential transformer, and I = ammeter reading corrected for scale error and multiplied by the corrected ratio of the current transformer. Then the apparent power factor is

$$\cos \theta_2 = \frac{P_2}{EI},$$

and the true power is

$$P = P_2 \frac{\cos (\theta_2 + \alpha + \beta + \gamma)}{\cos \theta_2}.$$

The angle θ_2 is to be taken positive when the current lags behind the voltage, and negative when the current leads. Note that α, β and γ may also be positive or negative angles. Values of the correction factor $\frac{\cos (\theta_2 + \alpha + \beta + \gamma)}{\cos \theta_2}$ are given in Tables I and II. Note carefully the conditions, stated at the head of each table, to which each table applies.

On three-phase systems (*see pp. 1824 and 1825*), when badly unbalanced, corrections should be applied separately, as above, to each wattmeter. When the circuit is balanced a single correction based on $\cos \theta_2$ for the whole circuit may be used.

TABLE I. CORRECTION FACTORS FOR PHASE ANGLE

$$\frac{\cos(\theta_2 + \alpha + \beta + \gamma)}{\cos \theta_2}$$

For lagging current when $(\alpha + \beta + \gamma)$ is positive
For leading current when $(\alpha + \beta + \gamma)$ is negative

$\alpha+\beta+\gamma$	Apparent power factor $\cos\theta_2$

Example No. 1. — Given a single-phase circuit with lagging current in which the wattmeter reading corrected for scale error and multiplied by the corrected ratios of current and potential transformers equals 24,520 watts, and the product of the voltmeter and ammeter readings, similarly corrected, equals 35,600 volt-amperes. Then $\cos \theta_2 = \frac{24,520}{35,600} = 0.688$ if the equivalent phase angle α of the wattmeter is $+4'$ and if from examination of characteristic curves the current transformer phase angle β is found to be $+48'$ and the potential transformer phase angle γ is $-10'$, then $\alpha + \beta + \gamma = +42'$, and from Table I, the correction factor is 0.9870. Whence the true power equals $24,520 \times 0.9870 = 24,201$ watts.

Example No. 2. — Given a single-phase circuit with leading current, in which the wattmeter reading, corrected as in example No. 1, equals 12,266 watts and the product of the voltmeter and ammeter readings, similarly corrected, equals 24,532 volt-amperes. Then $\cos \theta_2 = \frac{12,266}{24,532} = 0.5$. If the equivalent phase angle α of the wattmeter is $+5'$, the phase angle β of the current transformer $+2° 33'$ and the phase angle γ of the potential transformer is $+38'$, then $\alpha + \beta + \gamma = +3° 16'$ and therefore from Table II the correction factor to be used is 1.0971. Whence the true power equals $12,266 \times 1.0971 = 13,457$ watts.

Errors Due to Stray Fields. — Stray magnetic fields influence the reading of a wattmeter in much the same way as such disturbances influence the readings of other electrical instruments; see *Ammeters*. In unshielded instruments errors due to stray fields may be quite large. Considerable errors are often caused by the effect of neighboring instruments on one another. To avoid these errors some wattmeters are magnetically shielded.

ACCURACY OF WATTMETERS. — The question of the accuracy of electrical instruments is discussed in detail in the article on *Ammeters*. High-grade portable wattmeters may be obtained having a stated accuracy of 0.4 per cent of full-scale deflection, and when the readings are corrected in accordance with the calibration curve furnished with the meter, they may be relied upon to within 0.2 per cent of full-scale deflection. For example, if a single reading is 150 watts and the full-scale deflection is 500 watts, then the true watts will be between 149 and 151 watts. If the average of a number of readings is taken, this average will have a much greater degree of precision than the stated accuracy of the meter.

High-grade switchboard wattmeters may be obtained having a stated accuracy of 1 per cent of full-scale deflection. Of course the higher the degree of precision demanded the more costly is the meter.

TESTING OF WATTMETERS. — Wattmeters are usually tested by being compared with other standard wattmeters, which have in turn been examined by special methods and their behavior under various conditions of use determined. For examining the effect of low power factor on wattmeters phase-shifting transformers or generators having shifting fields are conveniently employed. By these means low power factor conditions may be produced on instruments without the necessity of troublesome adjustments of reactances, condensers, etc.

After a given instrument or type of instrument is known with certainty to give no sensible error on alternating current due to structural defects, it is usually more convenient to make subsequent checks to detect any change in the instrument by using direct current. The volts and amperes are in this case determined by means of suitable standard ammeter and voltmeter or by direct reference to potentiometer and standard cells; see *Potentiometers*.

MEASUREMENT OF THREE-PHASE POWER. — (*See also article by L. T. Robinson in General Electric Review, 1912, Vol. 15, p. 350.*) The measurement of the power supplied to a three-phase load may be effected in one or more of the following ways. The connections in each case may be made either directly or through proper instrument transformers, the latter being used for heavy currents and high voltages.

Single (One-element) Wattmeter on Three-wire System. — The current circuit of the wattmeter is connected in series with one of the mains supplying the load and the potential circuit of the wattmeter is connected between one terminal of the load and the neutral. If the neutral point of the load, or of the transformers supplying the load, is not available, a "Y-box" (see below) can be used to establish an artificial neutral. If the load is perfectly balanced (*see Alternating Currents*) the power input is then three times the wattmeter reading. However, a three-phase load is seldom sufficiently well balanced, even in the case of a three-phase motor load, to render this method of measurement an accurate one. In most practical cases it gives merely a rough approximation to the true power.

Y-Box. — The simplest form of Y-box consists of two equal non-inductive resistors connected in series, each of the free ends and the junction point being connected to a binding post. Each resistor has a resistance equal to that of the potential circuit of the wattmeter. One terminal of the potential circuit of the wattmeter is connected to the junction terminal of the Y-box and the other terminal of the potential circuit to the line wire in which the current circuit of the wattmeter is connected. The other two terminals of the Y-box are connected to the other two line wires respectively.

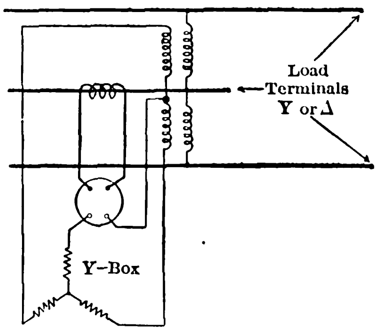

Fig. 3. Single-phase Wattmeter and Y-box for Three-phase Circuit

In the case of wattmeters designed especially for use with a Y-box, part of the resistance of the potential circuit of the wattmeter is placed in the Y-box, being connected permanently to the junction point between the other two resistors. A similar arrangement may be used as a multiplier. The connections of such a Y-box, wattmeter and instrument transformers are shown diagrammatically in Fig. 3.

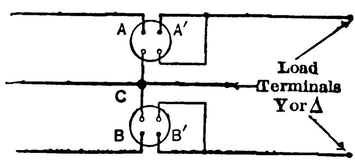

Fig. 4. Two Single-phase Wattmeters for Three-phase Circuits

Two-wattmeter Method for a Three-wire System. — The simple arrangement of two wattmeters shown in Fig. 4 will give exactly the total power in *any three-wire* circuit, provided each meter by itself gives accurate indications. Aside from the sources of error, as noted above, which may affect the accuracy of a meter on a single-phase circuit, the arrangement shown in Fig. 4 will give the true power for any condition of unbalancing, wave-form, frequency, etc. It is also immaterial whether the load be Y or Δ connected. The connections may be made directly as shown or through two

current transformers and two potential transformers, the connections being the same as in Fig. 5, except that two separate meters instead of a polyphase meter are used.

Rule for Adding or Subtracting Readings.—With the arrangement shown in Fig. 4 the total power is always the *algebraic* sum of the readings of the two wattmeters. Since a wattmeter reads only in one direction, usually to the right, the potential terminals of the two instruments must be so connected to the line that the needle of each instrument is deflected over the scale and not against the stop. For a balanced load having a power factor greater than 50 per cent, the sum of the two wattmeter readings, when the connections are thus made, gives the total power; for a power factor less than 50 per cent the difference of the two readings must be taken. When the power factor is not known, one can determine whether the readings should be added or subtracted by interchanging the two meters, leaving unaltered the potential connections to the third wire (C in Fig. 4); if the pointers of the two meters deflect in the same direction as before add the two readings, if the pointers deflect in the opposite direction (i.e., against the stop) subtract.

When the load is *balanced*, and the two wattmeters are connected, as in Fig. 4, so that each gives a positive reading, the question as to whether the power factor is above or below 50 per cent can be determined by changing the potential lead of the lower reading meter from the common connection C to the line in which the current coil of the other wattmeter is connected. If the reading thus obtained is positive, the power factor is more than 50 per cent and the readings should be added; if the reading is negative the power factor is less than 50 per cent and the readings should be subtracted.

Phase Difference between Voltage and Current in the Meter Windings.—In case the load is balanced it can be shown that if θ is the power-factor angle of the load, I the line current (current per wire) and E the line voltage (voltage between wires), then the power read by one wattmeter is

$$P_1 = EI\cos(\theta - 30),$$

and the power read by the other is

$$P_2 = EI\cos(\theta + 30).$$

The performance of the first wattmeter is the same as it would be on a single-phase load having a power factor of $\cos(\theta - 30)$ and the performance of the second meter is the same as it would be on a single-phase load having a power factor of $\cos(\theta + 30)$. These relations should be borne in mind when making any corrections for errors due to low power factor (see above).

Measurement of Power Factor by Two-wattmeter Method.—From the above relations it can be shown that the power factor of the load, when the load is balanced, may be calculated from the two wattmeter readings P_1 and P_2 by the formula

$$\text{Power factor} = 100\cos\left[\tan^{-1}\left(\sqrt{3}\,\frac{P_1 - P_2}{P_1 + P_2}\right)\right] \qquad \text{per cent,}$$

when the power factor is greater than 50%; and by the formula

$$\text{Power factor} = 100\cos\left[\tan^{-1}\left(\sqrt{3}\,\frac{P_1 + P_2}{P_1 - P_2}\right)\right] \qquad \text{per cent,}$$

when the power factor is less than 50%, P_1 and P_2 both being taken as positive in both cases and P_2 being the smaller reading.

Two-element Polyphase Wattmeter on Three-wire System. — Instead of using two separate wattmeters, as shown in Fig. 4, the two meters may be combined into a single meter with but one shaft and pointer. The connections for such a two-element meter, when instrument transformers are used, are shown in Fig. 5. For measurements where the power is badly fluctuating and especially when accompanied by low power factor, polyphase wattmeters may be more accurate and convenient. For ordinary polyphase service a polyphase wattmeter is not capable of as high accuracy as two single-phase wattmeters.

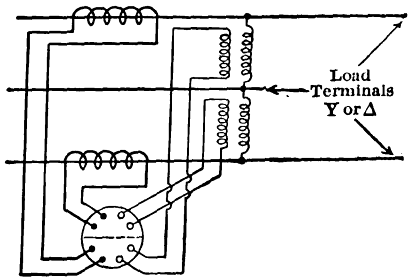

Fig. 5. Two-element Polyphase Wattmeter with Instrument Transformers

Determination of Power Factor with Two-element Wattmeter. — The two-element wattmeter reads directly the sum $P_1 + P_2$, using the notation in the previous paragraph. By reversing the connections of one set of potential terminals to the corresponding potential transformer the meter may be made to read $P_1 - P_2$. Hence by the use of a suitable reversing switch the power factor of the load may be readily determined by taking two readings; see preceding paragraph.

Three Wattmeters for Three-wire System. — As noted above, where two wattmeters, or a two-element polyphase wattmeter, are used on a three-wire system, the phase difference between the voltage and current in each meter or element may differ greatly from the power factor angle of the load. For example, in the case of a balanced load having a 50 per cent power factor, the current in one meter differs by 90° from the voltage on the potential circuit of this meter, and this meter should read zero watts, i.e., this meter operates under the worst possible conditions as regards power factor, and consequently the phase-angle error (see above), particularly when instrument transformers are used, may be quite large. It should be noted, however, that the reading of the meter or element in which the large phase difference occurs contributes proportionally less to the total reading as this phase difference approaches 90°, and consequently the percentage error of the total reading will be only a correspondingly small part of the error in this meter or element.

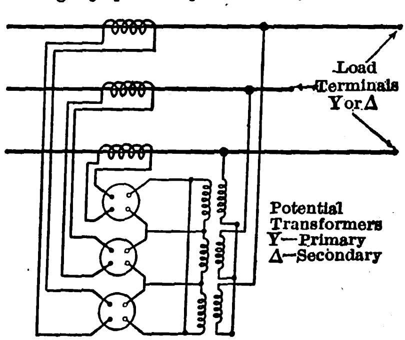

Fig. 6. Y–Δ Connections for Three Wattmeters on Three-wire System

Where the highest degree of precision is demanded, it is therefore advisable to use three meters connected as shown in Fig. 6. It should be noted, however, that for most practical purposes the very slight gain in accuracy by such an arrangement over the two-element meter does not justify the expense of the

additional meters and instrument transformers. Again, a precision measurement of power with the three-meter arrangement requires the accurate calibration and the accurate reading of three meters instead of one. The three-meter arrangement, however, possesses a practical advantage in that a failure of one or even of two of the meters may occur and still a fairly accurate determination of the power may be obtained from the meters or meter left in service.

Measurement of Power in Four-wire Circuits. — When part of the load current returns through a fourth wire, e.g., in an unbalanced three-phase system having a neutral wire, at least three wattmeters or wattmeter elements are required to obtain a theoretically accurate measurement of the power. A two-element meter, having three current circuits may be used for the measurement of power on a four-wire system, and under most circumstances will give results having as high a degree of precision as can be obtained with a two-element meter on a three-wire system.

When three meters are used, they should be connected in a manner similar to that used for two meters on a three-wire system, i.e., each of the three potential circuits should be connected between a main wire and the neutral wire, and each of the three current circuits should be connected in series with a main wire. When instrument transformers are used the primaries of the potential transformers are connected in Y, with the neutral point connected to the neutral wire, the three branches being connected to the main wires; the secondaries and the potential circuits of the meters are also connected in Y, with the meters Y-connected to the Y made by the secondaries.

Two-element Wattmeter on Four-wire System. — When used on a four-wire system the current coil of each element is divided into two sections, and one section of each current coil is connected in series with one section of the other coil, thus forming three groups of current coils. Each group is connected to a current transformer as shown in Fig. 7, which also shows the connections of the potential transformers, only two of which are required. With this arrangement the instrument measures correctly the power supplied by two branches of the system, but for the third branch the power measured is that corresponding to the current in this branch and the resultant (vector sum) of the voltages to neutral in the other two branches. Unbalancing of the system or badly distorted current and voltage waves will cause this resultant voltage to differ from the actual voltage to neutral in the third branch, producing an error in the measurement of this third of the total power. As noted above, however, this error is practically negligible under ordinary conditions unless the power must be measured with the highest degree of precision.

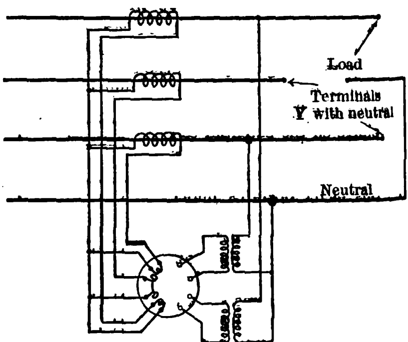

Fig. 7. Connections for Two-element Wattmeter on Four-wire System

GRAPHIC WATTMETERS. — These instruments are designed to draw on a chart a curve of power against time, without any appreciable time lag.

All instruments of this type consist of a wattmeter element and of a time element. The curve-drawing pointer is actuated either directly by the motion of the moving part of the wattmeter element, or indirectly on the relay principle through a system of contacts and solenoids. The purpose of the time element is to produce a steady motion of the paper at the point where the curve-drawing pointer (pen) is in contact with it. The clock, which turns the paper rolls, is either of the hand-wound type or of the electric self-winding type. In several types the rate of the paper feed may be varied from ¾ inch per hour to as high as 6 inches per minute.

Semi-portable forms of graphic wattmeters are on the market, but the more accurate instruments are for switchboard use only. Large errors due to friction between paper and curve-tracing pen or pointer, or due to change in level of the instrument, are not uncommon with certain types of graphic wattmeters.

COSTS, WEIGHTS AND DIMENSIONS OF WATTMETERS. — The following figures give a rough idea of the cost of wattmeters:

Indicating wattmeters	Portable	Switchboard
Single-phase:		
Low-grade	$25–$50	....
High-grade	$50–$100	$35– $50
Polyphase (two-element)	$100–$150	$60–$125

Current transformers are required when the current exceeds 200 amperes for single-phase or 50 amperes for polyphase wattmeters, and potential transformers are required when the voltage exceeds 600 volts for portable or 750 volts for switchboard wattmeters. Instrument transformers are also frequently used with lower voltages and currents.

A shielded single-phase switchboard wattmeter weighs about 10 lb., and has roughly the dimensions 8 in. by 8 in. by 5½ in. A shielded polyphase switchboard wattmeter weighs about 20 lb., and has roughly the dimensions 10 in. by 9 in. by 8 in. An unshielded single-phase wattmeter weighs about 4.5 lb. and has roughly the dimensions 7 in. by 6 in. by 4.5 in. Weights and dimensions of course vary with the make of the instrument.

[L. T. Robinson.]

WAVE ANALYSIS. — (*See also Alternating Currents.*) Any sine function y of a variable t, that is, any function of the form $y = Y \sin(\omega t + \phi)$, may be plotted as a wave, as shown in Fig. 1. The constant Y is called the

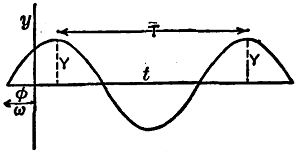

Fig. 1.

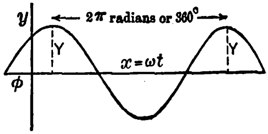

Fig. 2.

"maximum value" of the wave, the constant ϕ the "phase" of the wave, and the constant ω is called the "periodicity" of the wave. The distance between successive positive maxima (or between successive negative maxima) of such a wave is called the "period" of the wave, and is usually represented by the symbol T. The reciprocal of the period is called the "frequency," and is usually represented by the symbol $\frac{1}{T}$.

Period, frequency and periodicity are related as follows:

$$\omega = 2\pi f = \frac{2\pi}{T}.$$

The phase (ϕ) of the wave is also equal to the product of the periodicity by the distance to the left of the origin at which the wave first crosses the t axis in a *rising* direction; see Fig. 1.

In plotting a wave it is usually more convenient to take as the distance along the horizontal axis, not the value of the variable t, but the value of ωt. That is, putting $x = \omega t$, the equation for the wave may be written $y = Y \sin(x + \phi)$ and Fig. 1 then reduces to Fig. 2. When the wave is thus plotted the distance between successive positive maxima (or between successive negative maxima) is equal to 2π radians or 360°, and the phase is the distance to the left of the origin at which the wave first crosses the axis of x in the rising direction.

FOURIER'S SERIES. — Any periodic function y of a variable t may be plotted as a wave as shown in Fig. 3. If the function y and its first derivative with respect to t (that is, dy/dt) are finite and continuous for all values of t, then the function y may be represented by a series of terms of the form

$$y = Y_1 \sin(\omega t + \phi_1) + Y_2 \sin 2(\omega t + \phi_2) + Y_3 \sin 3(\omega t + \phi_3) + \text{etc.},$$

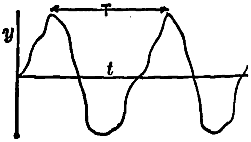

Fig. 3.

in which $\omega = 2\pi/T$, where T is the period of the given wave (i.e., the distance between successive positive, or between successive negative, maxima) and the Y's and ϕ's are constants. That is, the wave, no matter how complex, may be represented by the sum of a number of sine waves whose frequencies are even multiples of the period of the given wave.

This theorem is of great value in the theory of alternating currents (q.v.), since any alternating current or voltage satisfies the above conditions. The series is known as Fourier's Series.

As in the case of simple sine waves, it is usually more convenient in plotting

to take the distance along the horizontal, not the variable t, but the value of ωt. That is, putting $x = \omega t$, the series for y may be written

$$y = Y_1 \sin (x + \phi_1) + Y_2 \sin 2 (x + \phi_2) + Y_3 \sin 3 (x + \phi_3) + \text{etc.}$$

Fundamental and Harmonics. — The first term of the series, which has a frequency equal to that of the given complex wave, is called the fundamental. The succeeding terms, having frequencies which are multiples of the fundamental frequency, are called harmonics. For example, the third term, or the wave representing this term, has a frequency three times that of the fundamental and this term or sine wave is called the third harmonic, etc.

If the complex wave is such that the successive positive values of y for a positive half wave are numerically equal to the successive negative values of y for the succeeding negative half wave, only the *odd* harmonics occur. Such a wave is called a symmetrical wave. Voltage and current waves are usually symmetrical, and therefore contain only the odd harmonics.

DETERMINATION OF MAXIMUM VALUES AND PHASES OF THE HARMONICS BY INTEGRATION. — Consider the n th harmonic in the series

$$y = Y_1 \sin (x + \phi_1) + Y_2 \sin 2 (x + \phi_2) + Y_3 \sin 3 (x + \phi_3) + \text{etc.}$$

Plot the value of $u_n = y \sin nx$ between the limits $x = 0$ and $x = 2\pi$, and integrate the resultant curve, by planimeter, between these limits 0 and 2π. Call this area U_n. Similarly, plot the value of $v_n = y \cos nx$ between the limits $x = 0$ and $x = 2\pi$, and integrate the resultant curve, by planimeter, between these limits 0 and 2π. Call this area V_n. Then

$$Y_n = \frac{1}{\pi} \sqrt{U_n^2 + V_n^2}$$

and

$$\phi_n = \frac{1}{n} \tan^{-1} \left(\frac{V_n}{U_n} \right),$$

where the wave length of the fundamental corresponds to 360°. If the wave contains only the *odd* harmonics, as is usually the case in current and voltage waves (*see preceding paragraph*), U_n and V_n need be plotted only between the limits 0 and π. Calling U_n' and V_n' the corresponding areas, then

$$Y_n = \frac{2}{\pi} \sqrt{(U_n')^2 + (V_n')^2},$$

$$\phi_n = \frac{1}{n} \tan^{-1} \left(\frac{V_n'}{U_n'} \right).$$

This method, though cumbersome, is applicable to the determination of the maximum value and phase of any harmonic.

FISCHER-HINNEN METHOD OF ANALYSIS.— (*Elec. Journal, 1908, Vol. 5, page 386; Electrotechnische Zeitschrift, 1901, Vol. 22, page 396.*) This method is quite simple when the wave contains only the fundamental and the third, fifth and seventh harmonics. When even harmonics are present, or when there exist higher odd harmonics than the seventh, certain corrections must be applied. Since voltage and current waves usually contain only odd harmonics, and seldom contain higher harmonics than the seventh, the simple method without corrections is usually sufficiently accurate.

Waves Containing only the Third, Fifth and Seventh Harmonics. — To determine the nth harmonic (n equals 3, 5 or 7) divide the base of a half

wave into $2n$ equal parts and measure the ordinates of the wave at the beginning of each of these sections of the base. Call these ordinates y_1, y_2, y_3 . . . y_{2n}, taking the y's positive if above the base line, negative if below. y_1 will be zero, since the first section begins where the resultant wave crosses the base line.

Then the ordinates of this harmonic at the points 1 and 2 are, respectively,

$$A_n = \frac{1}{n}[(y_1 + y_5 + \ . \ . \ . \ y_{2n-1}) - (y_3 + y_7 + \ . \ . \ . \ y_{2n-3})],$$

$$B_n = \frac{1}{n}[(y_2 + y_6 + \ . \ . \ . \ y_{2n}) - (y_4 + y_8 + \ . \ . \ . \ y_{2n-2})].$$

The maximum value of this harmonic is

$$Y_n = \sqrt{A_n^2 + B_n^2},$$

and the phase angle, calling the wave length of the fundamental 360°, is

$$\phi_n = \frac{1}{n}\tan^{-1}\frac{A_n}{B_n}.$$

These formulas give the third, fifth and seventh harmonics ($n = 3$, 5 and 7 respectively). The fundamental is found by calculating

$$A_1 = -(A_3 + A_5 + A_7),$$
$$B_1 = y_0 + B_3 - B_5 + B_7,$$

where y_0 is the mid-ordinate of the half wave. Then

$$Y_1 = \sqrt{A_1^2 + B_1^2},$$
$$\phi_1 = \tan^{-1}\frac{A_1}{B_1}.$$

The equation of the given wave is then

$$y = Y_1 \sin(x + \phi_1) + Y_3 \sin 3(x + \phi_3) + Y_5 \sin 5(x + \phi_5) + Y_7 \sin 7(x + \phi_7).$$

The *effective* value of the given wave is

$$Y = \sqrt{\frac{Y_1^2 + Y_3^2 + Y_5^2 + Y_7^2}{2}},$$

and the *average* value is

$$Y_{\text{av'ge}} = \frac{2}{\pi}\left[Y_1 \cos\phi_1 + \frac{1}{3}Y_3 \cos 3\phi_3 + \frac{1}{5}Y_5 \cos 5\phi_5 + \frac{1}{7}Y_7 \cos 7\phi_7\right].$$

In using the above formulas strict attention must be paid to algebraic signs.

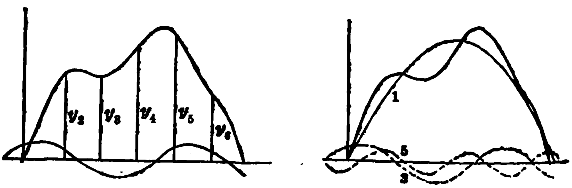

Fig. 4.

Example.—Find the third harmonic in the wave shown in Fig. 4. The values of the six ordinates are found by measurement to be 0, 676, 660, 940, 1004 and 554 respectively. Then

$$A_3 = \tfrac{1}{3}(1004 - 660) = 114.7,$$
$$B_3 = \tfrac{1}{3}(676 + 554 - 940) = 96.7,$$
$$Y_3 = \sqrt{(114.7)^2 + (96.7)^2} = 150,$$
$$\phi_3 = \tfrac{1}{3}\tan^{-1}\frac{114.7}{96.7} = 16.6^\circ.$$

Similarly, for the fifth harmonic,

$$A_5 = -92.8 \text{ and } B_5 = 37.4,$$
$$Y_5 = 100 \text{ and } \phi_5 = -13.6^\circ.$$

For the fundamental,

$$A_1 = -114.7 + 92.8 = -21.9,$$
$$B_1 = 940 + 96.7 - 37.4 = 999.3,$$
$$Y_1 = \sqrt{(21.9)^2 + (999.3)^2} = 1000,$$
$$\phi_1 = \tan^{-1}\frac{-21.9}{999.3} = -1.25^\circ.$$

Hence the complete expression for the given wave, taking as the origin the point at which the resultant wave crosses the base line in the rising direction, is

$$y = 1000\sin(x - 1.25^\circ) + 150\sin 3(x + 16.6^\circ) + 100\sin 5(x - 13.6^\circ).$$

The *effective* value is then 718 and average value 673.

Waves Containing Any Number of Harmonics, Odd or Even.—See *Electric Journal*, 1908, Vol. 5, p. 386.

[W. A. Del Mar and H. Pender.]

WAVEMETERS. — (*See also Wireless Telegraphy.*) By the wave length of an oscillation is meant the length of the wave which is set up by the oscillation in free space. Let λ be this wave length, f the frequency of the oscillation, and v the velocity of light in free space. Then

$$\lambda = \frac{v}{f}.$$

The velocity of light in free space is almost exactly 3×10^{10} (the average of the best measurements is 2.998×10^{10}) centimeters per second, or 300,000,000 meters per second, or 300,000 kilometers per second, or 984,000,000 feet per second, or 186,000 miles per second. Dividing this velocity by the frequency in cycles per second gives the wave length in the corresponding unit of length. For example, a frequency of 500,000 cycles per second gives a wave length of 600 meters or 1968 feet.

Practically all of the wavemeters, or high frequency meters, consist of a circuit containing inductance and capacity and an indicating instrument. By variation of the inductance or capacity, the wavemeter circuit can be brought to resonance (*see Alternating Currents*) with the oscillations the wave length of which is to be determined, and the indicating instrument tells when the resonant adjustment is attained. The meter may be made direct reading by utilizing a pointer moving over a properly calibrated scale.

Essential Elements of a Wavemeter. — Figs. 1, 2, 3 show the essential elements of a wavemeter. *C* is a variable capacity, *L* an inductance (which may also be variable) and *D* an indicating instrument. As an indicator we may use a low-resistance current detector (e.g., a hot wire ammeter, a thermo-

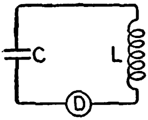

Fig. 1.

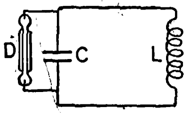

Fig. 2.

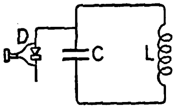

Fig. 3.

electric junction in shunt with a galvanometer, a low-resistance dynamometer, etc.), in series with the circuit as in Fig. 1, or a high-resistance detector (e.g., a Geissler tube) shunted around the condenser as in Fig. 2; or a high-resistance detector (e.g., a crystal detector in shunt with a high-resistance telephone) with but a single terminal connected to the condenser as in Fig. 3. In the latter case the capacity between the free terminal of the detector and the other terminal of the condenser is sufficient to permit the necessary current to flow through the detector.

To determine the frequency of the oscillation given out by an oscillation circuit, the wavemeter circuit is placed near the oscillation circuit in such a manner that a current is induced in the latter, and the capacity (or inductance) of the wavemeter is adjusted until the indicating instrument gives a maximum deflection or a maximum volume of sound or a maximum of light.

The wavemeter is usually calibrated by bringing it to resonance with various oscillation circuits of known frequency, the known frequency being obtained by calculation (*see Transient Electric Phenomena*), or preferably by revolving-mirror photographs of the spark of the oscillation circuit.

[G. W. PIERCE.]

WAVES, ELECTROMAGNETIC. — (*See also Detectors, Electric Wave; Wavemeters; Wireless Telegraphy; Wireless Telephony.*) Every variation of the current in an electric circuit produces a modification of the electric and magnetic forces in the neighborhood of the circuit. The modification of the electric and magnetic forces is propagated away from the source of the disturbance with a finite velocity and constitutes an "electromagnetic wave." If the variation of the current at the source takes place in a periodic manner, the modification of the surrounding electric and magnetic fields also occurs in a periodic manner, and gives rise to a series or "train of electromagnetic waves."

Electromagnetic waves may be guided by two parallel wires as in telephony and in alternating-current transmission, in which case the waves manifest themselves chiefly on the wires or in the immediate neighborhood of the wires; or the electromagnetic waves may be set free into space, as by the use of a Hertz "oscillator," in which case they become completely disconnected from all electric conductors and travel away as "electromagnetic radiation" in the dielectric; or, as a third possibility, the waves may be sent out over a partially conducting surface, as in the case of the electromagnetic waves of wireless telegraphy traveling over the surface of the earth, in which case the energy of the waves exists chiefly in the dielectric above the earth, but at the same time there are periodic electric currents induced in the earth.

APPLICATIONS. — Electromagnetic waves in dielectric media meet with their chief direct application to wireless telegraphy and wireless telephony, while electric waves on wires are the primary transmission factors of wire telephony. The electromagnetic wave phenomena associated with the transmission of electric power must be reckoned with in consideration of power losses and abnormal resonance rises of voltage.

THEORY. — Consider any point P in space, and let the coördinates of this point referred to three mutually perpendicular axes OX, OY and OZ be x, y and z, respectively. Let the positive sense of these three axes be fixed by the convention that OX points to the right of the page, OY to the top of the page and OZ out from the page toward the reader. Let

H = magnetic intensity at P,
B = flux density of magnetic induction at P,
F = electric intensity at P,
D = flux density of electrostatic induction at P,
u = current density at P,
ρ = volume density of electric charge at P,
k = dielectric constant at P,
μ = magnetic permeability at P,
c = velocity of light in centimeters per second in empty space $= 3 \times 10^{10}$,
t = time in seconds.

In addition, let all magnetic quantities be measured in abs. c.g.s. electromagnetic units and all electrical quantities in abs. c.g.s. electrostatic units, and let the subscripts x, y, z refer to the components of the various quantities in the direction of the three axes. Then, for any non-crystalline medium surrounding P, Maxwell (*Electricity and Magnetism*) shows that the following relations hold

$$\left.\begin{aligned} \frac{1}{c}\frac{\partial D_x}{\partial t} + \frac{4\pi u_x}{c} &= \frac{\partial H_z}{\partial y} - \frac{\partial H_y}{\partial z}, \\ \frac{1}{c}\frac{\partial D_y}{\partial t} + \frac{4\pi u_y}{c} &= \frac{\partial H_x}{\partial z} - \frac{\partial H_z}{\partial x}, \\ \frac{1}{c}\frac{\partial D_z}{\partial t} + \frac{4\pi u_z}{c} &= \frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y}, \end{aligned}\right\} (1) \qquad \left.\begin{aligned} -\frac{1}{c}\frac{\partial B_x}{\partial t} &= \frac{\partial F_z}{\partial y} - \frac{\partial F_y}{\partial z}, \\ -\frac{1}{c}\frac{\partial B_y}{\partial t} &= \frac{\partial F_x}{\partial z} - \frac{\partial F_z}{\partial x}, \\ -\frac{1}{c}\frac{\partial B_z}{\partial t} &= \frac{\partial F_y}{\partial x} - \frac{\partial F_x}{\partial y} \end{aligned}\right\}. \quad (2)$$

$$\frac{\partial D_x}{\partial x}+\frac{\partial D_y}{\partial y}+\frac{\partial D_z}{\partial z}=4\pi\rho. \quad (3) \qquad \frac{\partial B_x}{\partial x}+\frac{\partial B_y}{\partial y}+\frac{\partial B_z}{\partial z}=0. \quad (4)$$

$$\left.\begin{aligned} D_x &= kF_x, \\ D_y &= kF_y, \\ D_z &= kF_z. \end{aligned}\right\} \quad (5) \qquad \left.\begin{aligned} B_x &= \mu H_x, \\ B_y &= \mu H_y, \\ B_z &= \mu H_z. \end{aligned}\right\} \quad (6)$$

Wave Equation in Dielectric. — Assuming that the medium at the point x, y, z, is insulating, uncharged and at rest, and is non-crystalline, it may be shown by elimination among the equations (1) to (6) that each component of electric force and each component of magnetic force satisfies an equation of the form

$$\frac{k\mu}{c^2}\frac{\partial^2 M}{\partial t^2}=\frac{\partial^2 M}{\partial x^2}+\frac{\partial^2 M}{\partial y^2}+\frac{\partial^2 M}{\partial z^2}, \quad (7)$$

in which M is a general symbol for either of the quantities $H_x, H_y, H_z, F_x, F_y, F_z$. Equation (7) is called the "wave equation." Equation (7) may be simplified by restricting the disturbance to a plane distribution.

Plane Wave. — The assumption that each of the force components (indicated by the general symbol M) is a constant from point to point of a plane perpendicular to any given direction OP (Fig. 1) reduces the problem to a study of a plane wave. Let the position of the plane be designated by its distance x from an arbitrary origin O. Equation (7) then reduces to the form

$$\frac{k\mu}{c^2}\frac{\partial^2 M}{\partial t^2}=\frac{\partial^2 M}{\partial x^2}. \quad (8)$$

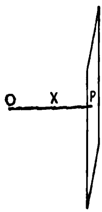

Fig. 1.

This equation is called the "plane-wave equation."

Solution of the Plane-wave Equation. — The general solution of equation (8) is of the same form as the solution of the equations of a transmission line (see p. 1678) having no resistance and no leakage, i.e., in which there is no attenuation. Without finding the form of the functions several important properties of the electric waves may be deduced. Some of these properties are here enumerated.

Velocity. — In any homogeneous dielectric medium at rest the electric and magnetic forces each travel with the velocity

$$v=\frac{c}{\sqrt{\mu k}}.$$

In empty space, $k = 1$ and $\mu = 1$; therefore in empty space the velocity

$v_0 = c$, the velocity of light.

Index of Refraction. — If a plane electric wave passes from empty space into a homogeneous medium of dielectric constant k (the medium being non-magnetic, i.e., $\mu = 1$) the velocity is changed from $v_0 = c$ to $v=\frac{c}{\sqrt{k}}$; therefore the index of refraction of the second medium for the electric waves is

$$n=\frac{v_0}{v}=\sqrt{k}.$$

Orientation of Electric and Magnetic Force. — In a homogeneous dielectric medium the electric and magnetic forces in a polarized electromag-

netic wave are perpendicular to each other and perpendicular to the direction of propagation of energy.

Reflection. — Perfect conductors are perfect reflectors of electromagnetic waves. For electromagnetic waves of a frequency of one million or more cycles per second, all ordinary metals are practically perfect reflectors.

Energy. — In a non-crystalline dielectric medium the energy of the wave as it travels forward is half electrostatic and half magnetic.

ELECTROMAGNETIC WAVES PRODUCED BY A HERTZ OSCILLATOR. — When the electric current is flowing in the direction from B to A in Fig. 2, the lines of electric force, such as are represented by the shaded loops, are in planes through the axis of the oscillator, while the lines of magnetic force are circles in planes perpendicular to the axis of the oscillator.

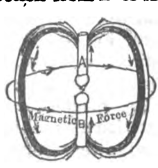

Fig. 2.

By treating the oscillator as a doublet, Hertz (*Electric Waves*) has computed the field of force around the doublet and has constructed the lines of induction from such an oscillator. A simplification of Hertz's diagram, in which only a few of the lines are drawn, is given in Fig. 3. This diagram represents approximately the condition of things at a particular instant. Up near the oscillator the lines of electric induction terminate on a plus charge on one half and a negative charge on the other half of the oscillator. Out farther from the oscillator the lines of electric induction are closed loops. These loops have been produced by successive oscillations of the current on the oscillator and have been liberated from the oscillator and are moving freely away. As these loops move away from the oscillator, they elongate and the force becomes less intense, but the width of the loops in the direction PP remains practically the same, so that if a receiver be placed in a fixed position in the equatorial plane the inductive action of the loops, as they pass, changes continuously from one direction to the other with a period equal to that of the oscillator. Associated with these lines of electric induction, and at right angles to them, are the lines of magnetic induction; and both the electric and the magnetic induction act together on the receiving resonator to produce electromotive force in it. The best position of a linear resonator for receiving the waves is parallel to the electric induction from the oscillator.

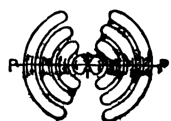

Fig. 3.

At a considerable distance from the oscillator the electric and magnetic inductions are in intensity inversely proportional to the distance from the oscillator. The factor of proportionality is, however, different along radial vectors to the oscillator making different angles with the axis of the oscillator.

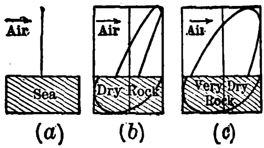
Very near the oscillator the electric and magnetic forces obey a different law with respect to distance.

PROPAGATION OF ELECTROMAGNETIC WAVES OVER A PERFECT CONDUCTOR. — The oscillation of an oscillator grounded to a plane perfect conductor of infinite extent and the radiation from such an oscillator is the same as the oscillation and radiation of the upper half of a symmetrical Hertz oscillator. Fig. 4 shows the lines of electric induction from the perfectly grounded oscillator. Since a line of electric induction must be a closed loop or must terminate upon a charge, there are induced in the surface of the conductor a series of positive and negative charges as shown in the figure. These positive and negative charges move away with the loops of induction and constitute cur-

Fig. 4.

rents in the surface of the conductor. The earth, where perfectly conductive, serves as a guiding conductor for the waves.

PROPAGATION OVER POOR CONDUCTORS. — A comparison of the conditions at points where the earth is a good conductor with conditions where it is a poor conductor has been made in a theoretical treatment of the subject by Professor Zenneck (*Ann. der Phys.*, *23, p. 846, 1907*). The result arrived at by Zenneck is typified in Fig. 5. Where the earth is a good conductor (for example, *sea water*) the electric force in the air above the water is perpendicular to the surface, as is shown in diagram (*a*), Fig. 5. This figure represents the direction of the electric induction (which in air is the same as the electric intensity). The magnitude of the induction at a stationary position is obtained by supposing the length of the line of diagram (*a*) to vary sinusoidally with the period of the waves. There would thus arrive at a station at sea a train of electric waves, and the force would be vertical and would go through a series of continuous oscillations. The force in the sea water below the surface would be zero.



(*a*) (*b*) (*c*)
Fig. 5.

Let us next suppose the waves to be traveling over a surface of a particular kind of dry rock. Professor Zenneck finds for this case that the electric force in the air above is by no means perpendicular to the surface and that not only the magnitude changes but the direction of the intensity also changes as the wave progresses. There is a similar intensity in the earth below, but different in magnitude and inclination. The condition is represented by the two semi-ellipses of diagram (*b*), Fig. 5. The electric intensity is obtained in magnitude and direction from (*b*) by taking the radius vector drawn from the center of the ellipse to a point moving around the ellipse with the frequency of the wave. The length and direction of the radius vector so drawn would represent the changing magnitude and direction of the electric intensity at a particular point with change of time. It is seen that such a radius vector has in general a vertical component and a horizontal component. The latter produces currents in the earth, and, if the earth is a poor conductor, causes absorption of energy.

Diagram (*c*) of Fig. 5 is obtained with a different quality of rock; that is, a rock of different conductivity of different specific inductive capacity, since both these constants enter into the treatment of the problem.

[G. W. PIERCE.]

WEIGHTS (MASSES) OF MATERIALS. — (*See also Mechanics, Principles of.*) The density of any substance is the mass of that substance per unit volume. Or, using weight in the ordinary sense as equivalent to mass, the density may also be defined as the *weight* per unit volume. The numerical value of the density of any substance depends upon the unit in which the mass or weight is expressed and also upon the unit of volume used; see *Units and Conversion Factors.* However, it is quite common to state the density of a substance in grams per cubic centimeter, without naming the units, since when so expressed the density is numerically equal (practically) to the specific gravity.

The "specific gravity" of a substance is defined as the ratio of the weight (mass) per unit volume of that substance to the weight (mass), expressed in the same unit of an equal volume of water. To make such a statement exact the temperature of the water should be specified. There is no general agreement as to the temperature of reference, though water at 0° C. is commonly taken as the reference temperature. For gases, air at 0° C. and 760 mm. mercury pressure is frequently taken as the reference substance instead of water.

Variation of Density of Water with Temperature. — The following table gives the results of measurements by Thiesen, Scheel and Diesselhorst (*Landolt, Börnstein and Roth, Physikalisch-chemische Tabellin, 1913*).

DENSITY OF WATER; GRAMS PER CU. CM.

Degrees Cent.	0	1	2	3	4	5	6	7	8	9

* Example: The density of water at 33° C. is 0.99473.

Weights per Cubic Foot and Specific Gravity. — In the following table are given the values of the density in pounds per cubic foot of the more commonly used substances. The specific gravity, or density in grams per cubic centimeter, corresponding to any weight per cubic foot w is equal to $w/62.43$; for the conversion factors necessary to convert these figures into densities for other units of mass and volume, see *Units and Conversion Factors.*

[H. PENDER and R. G. HUDSON.]

WIND PRESSURE. — (*See also Structures, Simple; Transmission Lines.*) Wind pressure is a subject upon which little exact information exists, although many experiments have been made and much study given to the subject by engineers and scientists. Among the unsettled questions are:

a. The relation between pressure and velocity.
b. The variation of pressure with size and shape of exposed plane surfaces.
c. The direction and intensity of pressure upon non-vertical surfaces.
d. The intensity of pressure upon non-planar surfaces.
e. The total pressure upon a number of parallel bars or other members placed side by side.
f. The decrease of pressure upon leeward surfaces.
g. The lifting power of the wind.

RELATION BETWEEN INDICATED (U. S. WEATHER BUREAU) WIND VELOCITY AND ACTUAL VELOCITY.—The indications of the anemometers used by the U. S. Weather Bureau do not give the *actual* wind velocity, but give values considerably higher than the actual velocities, as shown in the following table:

RELATION BETWEEN INDICATED AND ACTUAL WIND VELOCITY

Indicated Velocity, mi. per hr.	Actual Velocity, mi. per hr.	Indicated Velocity, mi. per hr.	Actual Velocity, mi. per hr.
10	9.6	60	48.0
20	17.8	70	55.2
30	25.7	80	62.2
40	33.3	90	69.2
50	40.8	100	76.2

In the U. S. Weather Bureau reports the indicated and not the actual wind velocities are given. However, as the anemometers used give the *average* velocity for several minutes, the instantaneous velocities due to sudden gusts may be considerably greater than the indicated velocities; the indicated velocity probably more nearly represents the "gust" velocity than the actual average velocity. In all calculations of maximum wind pressure it is therefore recommended that the *indicated* velocity be used.

RELATION BETWEEN PRESSURE AND VELOCITY. — The pressure varies about as the square of the velocity, the results given by different experimenters for the pressure due to a *normal wind on a plane surface* ranging from

$$P = 0.005\,V^2 \quad \text{to} \quad P = 0.0032\,V^2,$$

where P = pressure in pounds per square foot,
V = actual wind velocity in miles per hour.

The latter of these values represents the results of unusually careful experiments by Stanton (*see Minutes of Proceedings of the Institute of Civil Engineers, Vols. 156 and 171*) upon the intensity of pressure on plates varying in size from 25 to 100 square feet and is probably more nearly correct than the higher value. In the Stanton formula the values are reduced to correspond to a temperature of 60° F. and an atmospheric pressure of 14. 7 pounds per square inch.

The influence of size and shape of exposed surface is an important question and is not well understood, although it is known that the resultant pressure on a large surface may be taken as less per square foot than that on a small

surface, since the maximum intensity of the wind is due to gusts of comparatively small cross-section.

Formulas for Pressure on Plane Surfaces when Wind is not Normal. — The pressure upon vertical plane surfaces may be taken as normal to the surface and equal in intensity to the assumed wind pressure. Upon surfaces which are not vertical, the pressure is usually considered to be normal to the surface but lower in intensity than upon vertical surfaces. The variation in pressure with respect to the slope is not well understood and a number of empirical formulas are in use, among which are the Duchemin formula

$$P_n = P\frac{2 \sin i}{1 + \sin^2 i},$$

and the Hutton formula

$$P_n = P\,(\sin i)^{(1.84 \cos i - 1)},$$

where P = intensity of normal pressure upon the vertical surface,
P_n = intensity of normal pressure upon the given surface,
i = angle made by surface with the horizontal.

The following theoretical formula results from the assumption that the wind always blows in horizontal lines, and that if the pressure be resolved into normal and tangential components, the tangential component may be neglected:

$$P_n = P \sin^2 i.$$

This formula gives lower values than the empirical formulas and probably gives too low results since it makes no allowance for the reduction in pressure on the leeward side which is known to occur, and which may in part be attributed to the influence of the tangential component. It should also be noted that the wind does not blow uniformly in horizontal lines but may deviate considerably from the horizontal.

The values given by these three formulas are tabulated for comparison, using an assumed value of 30 pounds per square foot for P. In the absence of further experience upon this phase of wind pressure it would seem wise to use one of the empirical formulas instead of the theoretical one. The Hutton formula is used quite generally by structural engineers in England and the United States.

Pressure on Non-Planar Surfaces. — The pressure upon non-planar surfaces is important in the case of chimneys, standpipes, and other similar objects.

Upon the same assumptions as made in the preceding paragraph it may be demonstrated that theoretically the pressure on a cylinder is two-thirds of the total pressure on a plane diametrical section. This value is quite generally used. The pressures thus obtained lack experimental proof but are probably more nearly correct than the pressure obtained by the same method upon plane surfaces.

Effect of Reduction of Pressure on Leeward Side. — The pressure upon the windward side of an exposed surface is a function of the density and velocity of the air currents. The pressure on the leeward side is also a function of the shape of the surface, and has been shown by numerous experiments to be less than the static pressure of the air current. The resultant total pressure upon a surface is in consequence not only a function of the direct pressure on the windward side, but also of the pressure on the leeward side, which in turn is a function of the form of the surface. No algebraic formula can be given which will give the pressure on surfaces of varying shape with any considerable degree of precision.

Wind Pressure on Wires. — H. W. Buck (*Trans. Int. Elec. Cong., St. Louis, 1904, Vol. 2, p. 318*) gives the following formula for the pressure due to a normal wind on a stranded wire:

$$P = 0.0025V^2,$$

WIND PRESSURE IN POUNDS PER SQUARE FOOT

$P = 30$ pounds per square foot

Angle i, degrees	Theoretical $P \sin^2 i$	Duchemin $P \frac{2 \sin i}{1 + \sin^2 i}$	Hutton $P(\sin i)^{(1.84 \cos i - 1)}$
5	0.0	5.2	3.9
10	0.9	10.1	7.3

45	15.0	28.3	27.0
50	17.6	29.0	28.6
55	20.1	29.4	29.7
60	22.5	....	....
65	24.6	Above 60 deg.	Above 60 deg.
70	26.4	use 30 lb.	use 30 lb.
75	28.0		
80	29.1		
85	29.7		
90	30.0		

where P is the pressure in pounds per square foot of projected area of wire (length times diameter) and V is the velocity in miles per hour. This formula is based upon tests made on a 950-foot span at Niagara Falls; the wind velocities were measured by a U. S. Weather Bureau anemometer corrected to give actual average velocities.

PRACTICAL RULES FOR WIND PRESSURE ALLOWANCE.— The many uncertainties connected with wind pressure make worthless the attempts to specify with precision its magnitude and direction. In the lack of additional information and further theoretical studies there seems to be no reason for deviating from the common rules which have been used for many years with satisfactory results.

Bridges.—The portal, vertical and horizontal bracing are usually proportioned for a wind pressure of 30 lb. per sq. ft. on the surface of the applied load, and on the exposed surfaces of the floor system and both trusses. The pressure on the applied load is considered as a moving live load, and the other pressure as a dead load. For structures of ordinary spans the wind stresses are computed upon the unloaded structure for a pressure of 50 lb. per sq. ft. In the design the maximum stress computed by either of the above methods is used.

Buildings.—For wind pressure on roofs and buildings it is common practice to allow 30 lb. per sq. ft. acting horizontally upon the sides and ends of buildings, or on the vertical projection of roofs. It is also very important to figure the wind stresses on the steel frame considering it as an independent structure without walls, floors or partitions, since failures often occur in erection.

Transmission Poles and Towers.—For transmission towers a pressure as low as 13 lb. per sq. ft. has been used. This is perhaps warranted by the

fact that such towers are comparatively low and not exposed to the highest wind pressure. In the report of the Joint Committee on Overhead Line Construction (*Trans. N.E.L.A., 1911, Vol. 2, p. 521*) the following is recommended: "The wind pressure on the poles, or towers, shall be assumed at 13 lb. per sq. ft. of the projected area of solid or closed structures and 1½ times the projected area of latticed structures."

Wire Spans. — In the report of the Joint Committee just referred to it is recommended that the spans be designed for "a wind pressure of 8.0 lb. per sq. ft. on the ice-covered diameter (ice coating ½ inch in thickness), at a temperature of 0° F."

LIFTING POWER OF WIND. — In the case of a very rapid reduction of atmospheric pressure, as in a tornado, it is often observed that building roofs are lifted and walls blown outward. This phenomenon is due to the air in the building which is under more or less restraint, changing pressure less rapidly than the outside air and thereby producing a difference in pressure. This lifting action doubtless occurs to a greater or less degree whenever the external pressure is reduced, and should be guarded against by anchoring roofs securely to the walls.

[C. M. SPOFFORD.]

WIRELESS TELEGRAPHY.—(*See also Detectors, Electric Wave; Wave-meters; Waves, Electromagnetic; Wireless Telephony.*) In addition to the ordinary commercial and social correspondence between stations on land and sea, well-organized systems of time signals, storm warnings, and facilities for the collection and dissemination of weather statistics are maintained by the various governments, through the agency of wireless telegraphy.

Whenever an oscillating electric or magnetic field is set up electromagnetic waves are radiated into space. The amount of energy radiated will depend upon the form of the radiating circuit. It has been found that the best practicable form of radiating circuit consists of one or more vertical wires, from 50 to 1000 feet long, grounded through an inductance. The upper end of the vertical wire is also frequently connected to one or more horizontal wires, particularly for wireless stations on board ship. The vertical wire, together with the horizontal cradle, if any, is called the "antenna," or "aerial." The aerial and the inductance form together an "electric oscillator." The antenna and the earth form the two "plates" of a condenser, the dielectric between the two being the surrounding air. Such an oscillating circuit is therefore essentially a condenser and inductance connected in series.

Transmitting Circuits (Figs. 1 and 2).—In order to charge such an oscillator, a second coil is placed close to the coil forming the inductance, the two coils together forming an "oscillation transformer." This oscillation transformer

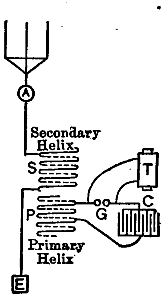

Fig. 1. Inductively-coupled Transmitting Station

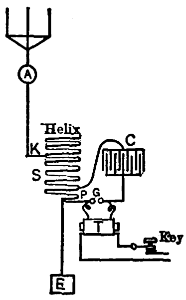

Fig. 2. Direct-coupled Transmitting Station

consists of but a few turns of heavy wire and is without iron. The two coils may be conductively independent, in which case the circuit is said to be "inductively coupled," as Fig. 1; or a single helix may be used, the entire helix forming the secondary and the primary being formed by a few turns tapped off from the helix as in Fig. 2, in which case the circuit is said to be "direct coupled." The primary of the oscillation transformer in either case is connected in series with a spark gap *G* and condenser *C*.

For the purpose of repeatedly charging the condenser *C* of either system, a step-up transformer *T* is used. The primary of *T* is connected through a key and through suitable regulating resistances or inductances with an alternating-current source of power. The secondary of the transformer *T* is connected about the spark gap *G*, or, what is the same thing, about the terminals of the condenser *C*.

Receiving Apparatus (Figs. 3 and 4).—The circuits of the receiving apparatus (of the inductively coupled type) are shown in Figs. 3 and 4. The corresponding

direct-coupled receiving circuits are not drawn. In Fig. 3, it is seen that the antenna is in series with an antenna inductance, a primary coil of an oscillation transformer, a series adjustable condenser and a ground. Oscillations produced in this antenna circuit by incident electric waves act inductively on the second-

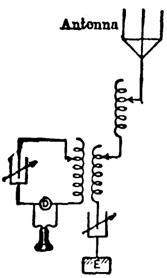

Fig. 3. Inductively-coupled Receiving Station with Detector in Secondary Circuit

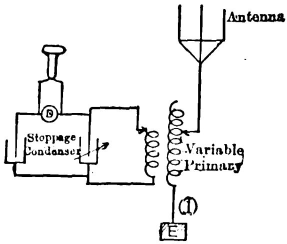

Fig. 4. With Detector in Shunt to Secondary Condenser

ary circuit containing the detector (*see Detectors, Electric Wave*), either in series with a condenser (Fig. 3) or in shunt with a variable condenser (Fig. 4). In this latter case another condenser, called a "stoppage condenser," shown at left of figure, is used to prevent the secondary of the receiving transformer from acting as a low-impedance shunt on the telephone receiver.

The various elements marked with arrows or arrow heads are adjustable for tuning.

THEORY. — The signals of wireless telegraphy are transmitted by electromagnetic waves sent out from the antenna of the transmitting station, and received by the antenna of the receiving station. The theory, therefore, comprises the theory of the oscillations that occur in the circuits, the theory of the propagation of the waves, and the theory of detectors. The last two subjects are discussed in the articles on *Waves, Electromagnetic*, and *Detectors, Electric Wave*. The theory of the oscillations occurring in the transmitting and receiving circuits is given briefly below.

Relation of Wave Length to Period. — If a source of oscillations has a period T of complete vibration and radiates energy in the form of waves, the wave length λ is the distance that the wave goes during one oscillation; whence

$$\lambda = vT, \tag{1}$$

in which $v =$ velocity of the waves. The velocity of electric waves in free space is the velocity of light, 3×10^8 meters per second, so that the wave length of a free wave in space is

$$\lambda = 3 \times 10^8\, T \text{ meters}, \tag{2}$$

where T is the period of the source in seconds.

In the case of an actual radiation of waves, this wave length λ will be the actual distance between two adjacent positions of similar phase in the train of waves radiated.

It has become customary in wireless-telegraphic practice to describe the period of oscillation of oscillatory circuits in terms of this free-space wave length, and this is done even though the circuit be of a form that radiates only an in-

considerable amount of its energy in the form of electric waves. For example, if a circuit has a period of 10^{-6} seconds, it is said to have a wave length of 300 meters (i.e., $3 \times 10^8 \times 10^{-6}$), even though the circuit be of such a form as to radiate practically no energy. See also article on *Wavemeters*.

Free Oscillation of a Circuit formed by a Lumped Inductance, Lumped Capacity and Resistance. — When a condenser of capacity C, and negligible leakage, discharges through an inductance L and a resistance R connected in series and all measured in the same set of units, the current oscillates with the period

$$T = \frac{2\pi\sqrt{LC}}{\sqrt{1 - \frac{R^2C}{4L}}} \text{ seconds,} \tag{3}$$

provided $\frac{R^2C}{4L} < 1$.

The equation for the current as a function of the time is, calling V_0 the initial p.d. of the condenser,

$$i = \sqrt{\frac{C}{L}} \frac{V_0}{\sqrt{1 - \frac{R^2C}{4L}}} \epsilon^{-\frac{\delta \cdot t}{T}} \sin 2\pi \frac{t}{T}, \tag{4}$$

where

$$\delta = \frac{RT}{2L}. \tag{5}$$

The constant δ is called the "logarithmic decrement." $100(1 - \epsilon^{-\delta})$ is the percentage decrease in the amplitude of the oscillation in one complete period.

Usually the effect of the resistance on the period of oscillation may be neglected, and equations (3) and (4) become, provided $\frac{R^2C}{4L}$ is negligible in comparison with unity,

$$T = 2\pi\sqrt{LC}, \tag{6}$$

$$i = \sqrt{\frac{C}{L}} V_0 \epsilon^{-\frac{\delta \cdot t}{T}} \sin 2\pi \frac{t}{T}, \tag{7}$$

where

$$\delta = \pi R \sqrt{\frac{C}{L}}. \tag{8}$$

It should be carefully noted that formulas (3) to (8) hold only for a circuit in which the capacity is "lumped." Also the formulas hold accurately only provided the circuit does not contain a spark gap (*see next section*).

Effect of Spark Gap on Period and Damping. — A spark gap is a resistance which varies with the current that flows through it. The greater the current through the gap, the less its resistance. In fact, the gap acts in such a manner as to oppose approximately a constant voltage to the discharge, instead of a constant resistance. This does not have much effect on the period of the discharge, but it materially changes the character of the damping, so that, in case the spark is the principal resistance in the circuit, the amplitude of the current of the condenser decreases linearly with the time, instead of

decreasing exponentially as is the case with constant resistance in the discharge circuit.

Free Oscillation of a Rectilinear Oscillator. — The antenna of a transmitting station has not only resistance, but also capacity and inductance, but the capacity and inductance are "distributed" instead of lumped. Such an antenna is approximately equivalent to a long, straight wire removed from all other conductors, and of length equal to twice the length of the antenna.

According to a theoretical investigation by Prof. Max Abraham (*Wied. Ann., Vol. 66, p. 435, 1898*), if such a rectilinear oscillator, long in comparison with its diameter and far removed from other conductors, is excited, by giving it an unequal distribution of charge, the free flow of current in it will have a period

$$\text{(Abraham's theory)} \qquad T = \frac{2l}{v} \text{ seconds,} \tag{9}$$

where l is the length of the oscillator in meters, and v is the velocity of light in meters per second $= 3 \times 10^8$.

Also, according to Abraham, the logarithmic decrement by radiation alone per complete period of such a rectilinear oscillator is

$$\text{(Abraham's theory)} \qquad \delta = \frac{9.74}{4 \log_e \frac{l}{d}} = \frac{2.435}{\log_e \frac{l}{d}}, \tag{10}$$

in which l/d is the ratio of the length to the diameter of the oscillator.

Several experimental tests of Abraham's formula (9) have been made, and such experiments, performed with or without a spark gap at the center of the oscillator, have given consistently values for the period which are somewhat higher than those calculated by formula (9). The experimental results are better represented by the equation

$$\text{(Experimental)} \qquad T = \frac{2.1\, l}{v} \text{ seconds.} \tag{11}$$

The departure of the experimental results from the theoretical values may be due to the fact that the theory presupposes that all other bodies are so far removed as not to have any influence on the period of the oscillator, — a condition which has not been attained in the experiments.

Free Oscillation of a Grounded Oscillator. — If the oscillator consists of a straight vertical wire grounded to a good conductor of practically infinite extent, the flow of current in the antenna (Fig. 5) is theoretically the same as if the ground were removed and replaced by a wire (dotted line) which is the reversed duplicate or image, of the antenna. The period is, therefore, according to equation (9), since the length of the antenna l is half the length of the equivalent free oscillator,

$$T = \frac{4l}{v}, \tag{12}$$

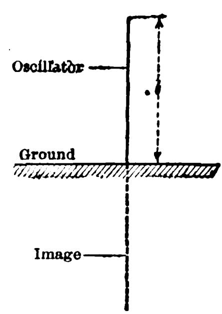

Fig. 5. Grounded Oscillator and Image

and the wave length is, theoretically,

$$\lambda = 4l. \tag{13}$$

The logarithmic decrement, by radiation alone, for such a grounded antenna,

if we accept Abraham's value of equation (10), and assume that the antenna radiates but that the image does not, is approximately

$$\delta = \frac{1.22}{\log_e \frac{2l}{d}}, \qquad (14)$$

in which l is length and d diameter of the oscillator.

The following table contains values of the radiation logarithmic decrement calculated from formula (14) for various lengths l and diameters d of vertical rectilinear oscillator.

TABLE I. — LOGARITHMIC DECREMENT BY RADIATION

l, meters	l, cm.	Diameter of wire in cm. = d				
		0.1	0.2	0.3	0.4	0.5
10	1000	0.123	0.134	0.140	0.142	0.147
20	2000	0.115	0.123	0.129	0.133	0.136
30	3000	0.111	0.118	0.123	0.127	0.130
40	4000	0.108	0.116	0.120	0.123	0.126
50	5000	0.106	0.113	0.117	0.121	0.123

These values give approximately the logarithmic decrement of a single grounded vertical wire calculated by equation (14). This decrement is due solely to radiation of electromagnetic waves of wave length approximately four times the length of the antenna. This decrement will be increased by the heat losses from the wire due to the heating of the conductor by the currents in it. These heat losses are in the form of electromagnetic waves of small wave length; i.e., wave length of the order of 0.01 to 0.0001 millimeter. The decrement due to heat losses may, however, be small in comparison with the decrement due to the long electromagnetic waves.

Equivalent Lumped Inductance and Lumped Capacity of an Antenna. — Although the inductance and capacity of the aerial circuit is distributed, it has been shown by experiment that as far as the period, amplitude and logarithmic decrement of the oscillations are concerned, the aerial circuit may be considered as replaced by an equivalent lumped inductance and capacity, and the formulas given above ((6) to (8)) for lumped inductance and capacity may be employed. To determine this equivalent inductance L_0 and capacity C_0, an inductance L is inserted in the aerial circuit near the ground (i.e., at the loop of current) and the period of the waves sent out from the oscillator with this added inductance is measured by a wavemeter (*see Wavemeters*). Call this period T; then, from (6),

$$T = 2\pi\sqrt{(L + L_0)\,C_0}.$$

The added inductance is then changed to a new value L_1, and the corresponding period T_1 measured by the wavemeter. From (6)

$$T_1 = 2\pi\sqrt{(L_1 + L_0)\,C_0}.$$

From these two equations L_0 and C_0 may be calculated.

Effect of Introducing Inductance or Capacity in Series with an Antenna. — From formulas (6) and (8) it is apparent that introducing an inductance into the antenna near the ground increases the period and wave length and decreases the logarithmic decrement. Inserting a condenser C in series in the aerial circuit near the ground decreases the resultant capacity, since this resultant capacity becomes (two condensers in series) $\frac{C_0C}{C_0+C}$. Therefore, from (6) and (8), it is apparent that the insertion of a condenser in the aerial decreases the period and wave length and increases the logarithmic decrement. The substitution of the resultant capacity $\frac{C_0C}{C_0+C}$ in (6) and (8) gives the new period and logarithmic decrement only to a rough approximation, since the introduction of the capacity C also changes the equivalent capacity of the antenna.

Free Oscillations in Coupled Circuits. — The free oscillation of two circuits coupled together as in Fig. 6 is doubly periodic; the current in the primary circuit and also the current in the secondary circuit both have two periods, resulting in beats, as shown in Fig. 7.

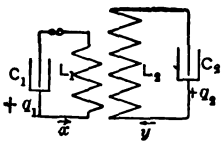

Fig. 6. Coupled Condenser Circuits.

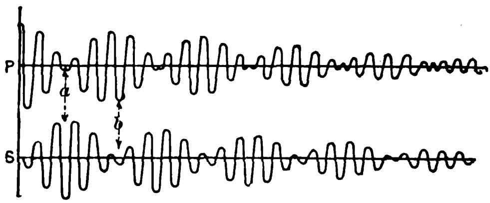


Primary and Secondary, Ordinary Spark

Fig. 7. Showing Double Periodicity

As is seen in Fig. 7, the current in the primary oscillates at the beginning with a large amplitude, and that in the secondary has at the beginning a small amplitude; then at each oscillation the current in the primary decreases in amplitude, and that in the secondary increases until the condition at a is reached, in which the current in the primary is practically zero, and all of the energy is in the secondary. Then, as the oscillations continue, the energy comes back into the primary (condition b), etc.

If T_1 is the period of one of the circuits called the *primary* when alone, T_2 the period of the other circuit (the *secondary*) alone, then, if we neglect the influence of damping on period, the two periods of *each circuit when coupled together* are

$$T_1' = \sqrt{\frac{T_1^2 + T_2^2 + \sqrt{(T_1^2 - T_2^2)^2 + 4\tau^2 T_1^2 T_2^2}}{2}},$$

$$T_2' = \sqrt{\frac{T_1^2 + T_2^2 - \sqrt{(T_1^2 - T_2^2)^2 + 4\tau^2 T_1^2 T_2^2}}{2}}, \qquad (15)$$

in which τ, called the "coefficient of coupling," is

$$\tau = \sqrt{\frac{M^2}{L_1 L_2}}, \qquad (16)$$

where

M = mutual inductance between the circuits.
L_1 = self inductance of the primary,
L_2 = self inductance of the secondary.

The equations (15) have been obtained theoretically by neglecting th effect of the damping of the circuits in modifying their periods, and hav confirmed experimentally.

The wave lengths of the two circuits may be obtained by multiply periods by the velocity of light, and give the result

$$\lambda_1' = \sqrt{\frac{\lambda_1^2 + \lambda_2^2 + \sqrt{(\lambda_1^2 - \lambda_2^2)^2 + 4\tau^2\lambda_1^2\lambda_2^2}}{2}},$$

$$\lambda_2' = \sqrt{\frac{\lambda_1^2 + \lambda_2^2 - \sqrt{(\lambda_1^2 - \lambda_2^2)^2 + 4\tau^2\lambda_1^2\lambda_2^2}}{2}},$$

in which λ_1 and λ_2 are the wave lengths of the two circuits respectivel standing apart so as not to influence each other, and λ_1' and λ_2' are derived wave lengths obtained when the circuits are coupled together.

An interesting special case arises when the two circuits are equiperiod standing alone; that is when $\lambda_1 = \lambda_2 = \lambda$ (say). In this case, equatio become

$$\lambda_1' = \lambda\sqrt{1+\tau},$$

$$\lambda_2' = \lambda\sqrt{1-\tau}.$$

Free Oscillation of an Antenna Circuit Coupled with a Con Circuit. — Likewise, when a condenser circuit is coupled with an ante cuit, as in Figs. 1 and 2, the oscillation is generally doubly periodic, with periods of oscillation ~~and~~ wave lengths given approximately by the ec (15), (16), (17); and if the two circuits, when standing alone, have t period as each other, the derived periods are approximately related to th period by the equations (18).

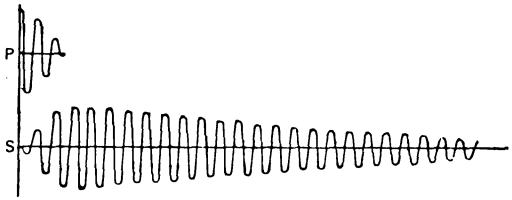
These several formulas are derived by considering the inductance and of the antenna as lumped, and the approximation is fairly close when t comparatively large inductance in the antenna helix (cf. Figs. 1 and 2), the distributed inductance is small in comparison. In circuits where t dition is not fulfilled the quantitative relations of equations (15) to (be used only to get a general insight into the manner in which the together of circuits affects their oscillation.

Effect of Quenched Spark. — If the condenser circuit of a coupled station contains a quenched spark gap (described below), the oscill doubly periodic only for the short interval that the spark persists. W oscillation reaches the primary minimum, at *a* in Fig. 7, the spark of the q gap becomes extinguished and does not relight. In consequence the circuit ceases to influence the oscillation of the antenna, which goes on ing with its own free period.

This condition is shown in Fig. 8. The quenched-gap method of e possesses the advantage of avoiding the successive return of energ primary where it is continually dissipated as heat in the gap and in the circuit. It possesses also the further advantage that the system em a single wave length and thereby is adapted to sharper tuning than system emitting two waves. A third advantage of the quenched gap

the fact that it operates at low potential and high spark frequency, thereby diminishing the breakage of transmitting condensers.

The quenched gap consists of a series of very short discharge spaces between



Primary and Secondary, Quenched Spark

Fig. 8. Current Plotted against Time with Quenched-spark Excitation

heavy copper disks held apart by thin gaskets of paper, or rubber or other insulating material. The large metal disks afford rapid cooling of the gap, and the exclusion of air from the discharge spaces seems to facilitate the rapid extinction of the spark when the beat-zero of oscillation is reached in the primary.

POWER REQUIRED TO OPERATE TRANSMITTING STATION. — The primary condenser (C, Fig. 1) of the sending station is charged from a step-up transformer. The power at the terminals of secondary of the transformer required to operate the station is

$$P = \frac{nCV^2}{2} \text{ watts,} \tag{19}$$

in which C is the capacity of the condenser in farads, n is the number of charges of the condenser per second, and V is the p.d. of the condenser at the beginning of the spark. If one spark occurs at each alternation of the supply current, n is twice the number of cycles per second f of the supply current; i.e., $n = 2f$. If, on the other hand, more than one discharge takes place during each half cycle, n is greater than twice the number of cycles per second. In some of the largest transmitting stations the power required amounts to as much as 60 kilowatts. In an ordinary ship's installation from 3 to 15 kilowatts are used.

The power given by equation (19) is that required to operate the station. The power actually radiated is very much less than this, ranging from 5 per cent to 50 per cent of the power input. Because the maximum sensitiveness of the telephone receiver used in receiving signals lies in the neighborhood of 1000 cycles per second, it is now good practice in wireless-telegraphic engineering to use alternating-current generators of about 500 cycles and arrange the spark gap to give one spark at each alternation of the generator; that is, 1000 sparks per second.

However, on account of the economy in using sources of power already available, which are usually of 60 or 120 cycles, these frequencies of alternating current are still extensively used in wireless telegraphy.

DESIGN OF CONDENSERS FOR TRANSMITTING STATION. — The following table (Table II) contains values of transmitting condenser capacity computed from equation (19) for use in a 5-kilowatt sending station, with various cycles and sparking voltages across the gap. Two sparks per cycle are assumed and the discharge voltage of the first column is the instantaneous voltage at which the discharges occur, when the key is held down.

TABLE II

CAPACITY OF CONDENSER FOR 5-KW. STATION

Discharge voltage	Capacity in microfarads required for various cycles per second					
	60 ~	120 ~	200 ~	300 ~	400 ~	500 ~
10,000	0.833	0.417	0.250	0.167	0.125	0.100
15,000	0.371	0.186	0.111	0.0743	0.0556	0.0445
20,000	0.208	0.104	0.0625	0.0417	0.0312	0.0250
25,000	0.133	0.067	0.0400	0.0267	0.0200	0.0160
30,000	0.093	0.0465	0.0278	0.0185	0.0139	0.0111
35,000	0.068	0.0340	0.0204	0.0136	0.0102	0.0082
40,000	0.052	0.0260	0.0156	0.0104	0.0078	0.0062
45,000	0.041	0.0206	0.0123	0.0082	0.0062	0.0049
50,000	0.033	0.0166	0.0100	0.0067	0.0050	0.0040
55,000	0.028	0.0137	0.0082	0.0055	0.0041	0.0033
60,000	0.023	0.0116	0.0070	0.0046	0.0035	0.0028

Since the capacity required is proportional to the power, the value of the capacity required for a station of any other power, *P* kilowatts, is equal to that given in the table multiplied by $P/5$. In designing condensers for the transmitting station it is necessary to allow for abnormal voltages in starting the spark. Good Bohemian glass may be submitted to a potential difference of about 11,000 volts per millimeter of thickness. Ordinary window glass is capable of standing about the same electrical stress. Plate glass, which is usually a lead glass, is much weaker. Assuming the breaking strength of a good glass to be 11,000 volts per millimeter of thickness, the following table (Table III) is computed for the physical dimensions of condensers for a 5-kilowatt station, with the cycles and discharge voltages of Table II. The table is given in terms of the number of sheets of dielectric required, when the metallic coating of the two opposed plates has an area of one square foot, the thickness of the dielectric plates being computed to stand a potential difference of 2.5 times the operating potential.

These condenser values are for a 5-kilowatt station. The number of plates for a station of any other power, *P* kilowatts, can be obtained by multiplying the numbers in the appropriate columns of Table III by $P/5$.

The glass for these condensers should be selected for absence of blowholes and other defects, and, if the plates are piled up, the glass plates, which are likely to be curved, should be placed with convex side of one piece against concave side of adjacent piece to avoid breakage from mechanical pressure. The metallic coatings of the glass should preferably be of copper and should be plated upon the glass.

Leyden jars, copper plated, are on the market, and have about the same breaking strength as the plates above described and may be assembled to give the required capacity and strength.

The last column of Table III contains the width of margin required for the condensers when the plates are in air. If the condensers are submerged in castor oil, having been built up under the oil, the margin may be reduced to about one-half the values given in the table.

TABLE III

DIMENSIONS OF CONDENSER FOR 5-KW. STATION

Discharge potential in volts	Potential at start (assumed) in volts	Required thickness of glass		Capacity per sq. ft. of conductor in microfarads	No. of these plates required at various cycles							Width of margin on each side of plate in in.
		mm.	in.		~ 60	~ 100	~ 120	~ 200	~ 300	~ 400	~ 500	
10,000	25,000	2.3	0.090	0.00250	333	200	167	100	67	50	40	1.0

DESIGN OF CHARGING TRANSFORMER. — Accurate engineering data for the design of the transformer for charging the sending condenser are, so far as the writer knows, not available. A closed iron core without magnetic leakage should not be used, for the reason that such a transformer draws more power on short circuit than it does when its secondary is charging the condenser; and, in consequence, when the spark is started the power input increases and maintains the spark as an arc across the gap, so that the condenser does not again charge. What is required is a resonance transformer, — one with magnetic leakage, so designed that when the spark starts, the transformer circuit is thrown out of resonance by the spark and thus cuts off the power supply, so that the spark may extinguish and the condensers again charge. This is attained by an open-core transformer, or by one with an E-shaped core designed to have magnetic leakage between the primary and secondary windings. A calculation of the current-carrying capacity required of the secondary windings may be made as follows:

The average value of the current required to charge the condenser n times per second to a voltage V is nVC, where C is in farads. Substituting for C its value in terms of P from equation (19), the average secondary current in amperes is $\frac{2P}{V}$.

It is difficult to say just what is the form of cycle of the current flowing into the condenser, and it is therefore difficult to estimate the effective value of the secondary current. Assuming that the current is sinusoidal for 90° then zero for 90°, the effective value I_s of this current is found to be $\frac{\pi}{2}$ times the average value, or

$$I_s = \frac{\pi P}{V} \text{ amperes,} \tag{20}$$

if the sending key is held down continuously. In equation (20) P is power in watts supplied to the condenser, V is volts at which condenser discharges, and I_s is the effective current in the secondary of the transformer.

Since in general the sending key will be held down only at intermittent intervals, the actual effective current will be considerably less than that given by equation (20). This equation should therefore be used as the limiting maximum value of this current.

WIRELESS TELEPHONY. — (*See also Wireless Telegraphy.*) The circuits employed in wireless telephony resemble closely those used in wireless telegraphy. The receiving circuits and their appendages are identical for telephony and for telegraphy, so that a receiving wireless-telegraph station, when operating with any of the rectifier detectors (with a telephone receiver as indicating instrument), is suitable for receiving either telegraph or telephone messages. The high-frequency circuits at the transmitting station are also of the same general character for telephony and for telegraphy, but the ordinary spark-discharge method of excitation at the transmitting station is not applicable for wireless telephony, for such excitation produces discrete trains of oscillations, which, arriving at the receiving station, are rectified by the detectors, and give discrete impulses of rectified current to the telephone receiver. These discrete impulses used in wireless telegraphy are usually within the range of audibility and produce a musical note at the receiver. This musical note would predominate over any modifications impressed by speech at the transmitting station.

In order to adapt the transmitting station of wireless telegraphy to wireless telephony, it is necessary to change the excitation at the sending station, so that the waves emitted shall be a continuous sequence, or, if discrete, shall follow one another at a frequency above the limit of audibility.

When such a persistent sequence of waves arrives at the receiving station, it is rectified by the detector, and gives a practically continuous pull upon the diaphragm of the telephone receiver, and is not audible except for such accidental irregularities of audible frequency as arise in imperfections of the exciting generators. Now, if such persistent oscillations at the transmitting station are caused to pass through a carbon microphone, or similar instrument, and the resistance of the microphone is caused to vary by the voice, the sequence of waves is modified in intensity, so that the amplitude of the high-frequency sequence of waves carries with it a series of modifications, or modulations, corresponding to the pitch, intensity and quality of the voice. These modulations persist also in the rectified current through the receiving telephone and are heard as spoken words.

The main problem of wireless telephony, is, therefore, the production of a sequence of high-frequency oscillations at the transmitting station of such persistence and regularity as not to have any variations of audible frequency.

GENERATORS FOR PERSISTENT HIGH-FREQUENCY OSCILLATIONS. — Among the generators for persistent high-frequency oscillations may be mentioned: (1) the high-frequency alternator, (2) the Poulsen arc, and (3) the Chaffee gap.

High-frequency Alternators. — A high-frequency alternator capable of giving 100,000 cycles per second is manufactured by the General Electric Company. It is driven by a 10-horse-power electric motor geared to the alternator by a De Laval turbine gear, giving the inductor of the alternator a speed of 20,000 revolutions per minute. The machine contains a stationary field, a stationary armature and a rotating inductor. The air gap of the machine may be varied by means of a micrometer screw attached to the frame of the machine. The machine is intended to be used with a resonant condenser, and gives, when so used, a terminal voltage of from 150 to 300 volts. The power output is about 5 kilowatts.

The Goldschmidt High-frequency Alternator (Fig. 1). — Another type of high-frequency alternator has recently been developed by R. Goldschmidt in Germany for giving from 30,000 to 100,000 cycles per second with a much slower speed of the rotating part. This is done by a combination of the effects of rotation with the effects of resonance, and results in raising the frequency of the

generator to a multiple of its normal frequency. In Fig. 1, S represents the windings on the stator and R the windings on the rotor. Suppose that the number of poles of the stator and rotor are designed so as to give a frequency f when the machine is used as an ordinary alternating-current generator with direct current in the stator. The frequency f may be of the order of 10,000 cycles without excessive speed. In order to get higher frequencies from the machine, a choking coil D is placed in the direct-current feeding circuit, B, D, S, and condensers C_1 and C_2 are shunted with the field, and other condensers C_3, C_4 and C_5 are attached to the slip rings of the rotor.

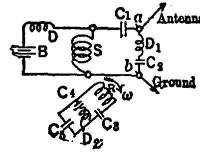

Fig. 1. Diagram of Circuits in Goldschmidt's Alternator

The machine operates on the principle that when an alternating current flows in the field coils the frequency of the rotor e.m.f. is the sum of the frequency of the alternating field and the frequency which would be induced in the rotor were a steady-current field used. This principle is used in connection with resonance methods for accentuating the required multiple frequencies.

The inventor claims that a machine of this type has been in operation since 1910, and that it furnishes 12.5 kilowatts at 30,000 cycles with an efficiency of about 80 per cent, and that it delivers about 8 to 10 kilowatts at 60,000 cycles. He claims that there is no difficulty in constructing machines on the same principle capable of giving 60 to 80 kilowatts.

Poulsen's Arc Generator for High-frequency Oscillations (Fig. 2).—This device consists of a copper-carbon arc in an atmosphere of coal gas or hydrogen. Details of the arc and its circuits are shown in Fig. 2. The copper terminal, which is usually hollow and water-cooled, is the positive terminal of the arc. The negative terminal of carbon is slowly rotated by clockwork. The gas receptacle surrounding the arc is provided with a worm carrying water for cooling the walls of the receptacle. The poles of a powerful electromagnet are inserted gastight, into the chamber, and placed so as to give a strong magnetic field transverse to the arc. The circuits are as follows: The leads from a direct-current dynamo of from 200 to 500 volts are brought through a control resistance and around the coils of the electromagnet and connected to the terminals of the arc, so that the copper terminal is positive. About the arc a circuit consisting of a condenser C and self inductance P are shunted. Oscillations are set up in this circuit and act inductively upon a secondary coil S attached to an antenna and ground. (*See also Arc, Electric.*)

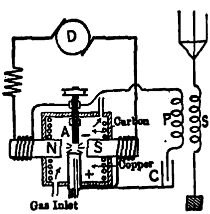

Fig. 2. Poulsen Arc-generator

At 100,000 cycles the Poulsen arc is capable of delivering several kilowatts of high-frequency power. It is difficult to get frequencies much above 200,000 cycles with this form of generator.

The Chaffee Gap for High-frequency Oscillations (Fig. 3).—A gap devised by E. L. Chaffee for producing high-frequency oscillations consists of a minute gap in hydrogen between a copper anode and an aluminum cathode. The copper terminal is shown in section at e in Fig. 3. A terminal of the same size but made of aluminum is shown facing e. Except for the difference in the metal of the two terminals, the two halves of the gap and mounting are symmetrical. Each terminal is inserted in a heat-radiating support t. The two supports are separated by an insulating block, which contains a small cavity

in which the arc is surrounded by an atmosphere of hydrogen. The gap operates on from 220 to 500 volts, and is fed from a direct-current source through a choking coil. A condenser and inductance are shunted about the gap. This condenser and inductance with the gap constitute the primary of the oscillation system. The secondary of the system consists of a secondary coil and an antenna and ground as in Poulsen's arrangement of circuits. However, in the Chaffee device the primary circuit is not an oscillation circuit, for the gap is a rectifier and permits only direct-current impulses flowing in a direction from the copper to the aluminum through the gap. One of these impulses starts the secondary circuit oscillating, and the secondary oscillations impose potential ripples on the primary so as to trigger off successive primary impulses at just the proper time for maintaining the secondary current. The recurrence of the primary impulses may be made of any desired frequency with respect to the secondary current by adjusting the primary condenser and inductance and the main supply current. The Chaffee gap may be used to develop any frequency up to 30,000,000 cycles per second. At 1,000,000 cycles a single gap will give about ½ kilowatt of high-frequency power.

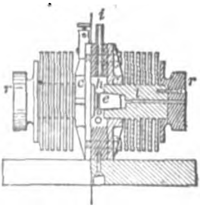

Fig. 3. Chaffee Gap

CONNECTIONS FOR TRANSMITTING STATION. — Figs. 4, 5 and 6 show connections for a wireless telephone transmitting station with an arc as source of oscillations. When one of the high-frequency alternators is to be

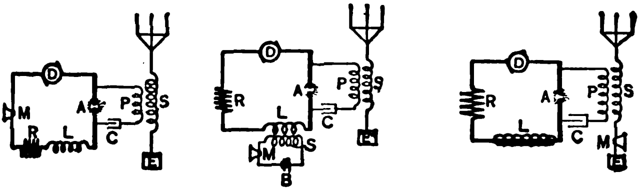

Fig. 4. Fig. 5. Fig. 6.

Types of Connections for Wireless Telephone Transmitting Stations

used, the alternator terminals are connected to the leads to *C* and *P* respectively. These diagrams are introduced particularly to show the disposition of the microphonic transmitter *M*. The best position for this transmitter is directly in series between the secondary coil *S* and the ground *E*, as in Fig. 6. Other arrangements are with the transmitter in series with the dynamo circuit through the arc, as in Fig. 4, or in a circuit *B*, *M*, *S* (Fig. 5), arranged to act inductively upon the dynamo circuit. Another disposition of the microphone, not shown in the figures, is in a tertiary circuit inductively coupled with the antenna circuit.

The microphone for wireless telephony must be of large current-carrying capacity and in consequence water cooling in the transmitter is sometimes resorted to.

TRANSMISSION DISTANCE. — The wireless telephone, though not in general use, is easily practicable up to distances of 100 miles.

WIRES AND CABLES, BARE. — *(See also Aluminum; Copper; Gages, Wire; Resistance and Conductance; Standardization Rules of the A.I.E.E; Wires and Cables, Insulated; Wires, Resistance.)*

The following is a brief table of contents of this article:

A wire may be either solid or stranded, i.e., made up of a number of smaller wires twisted or braided together. A large bare stranded wire is usually called a bare cable. Data on the insulation and protection of wires and cables will be found in the article on *Wires and Cables, Insulated*. Data on resistance wires will be found in the article on *Wires, Resistance*, and data on the properties of the various metals will be found in the articles on *Aluminum, Copper*, and *Steel*.

PER CENT CONDUCTIVITY. — The definitions, constants and tables in this article are all in accord with the 1914 edition of the *Standardization Rules of the A.I.E.E.* (q.v.). Per cent conductivity refers to the "International Annealed Copper Standard." On the assumption of a resistivity temperature coefficient of 0.00393 at 20° C. this per cent conductivity is only 0.283 per cent higher than the conductivity referred to Matthiessen's Standard (*see Resistance and Conductance*. If the length of a given wire is L cm., its cross-section A sq. cm. and its resistance at 20° C. is R_{20} ohms then the per cent conductivity of this wire is

$$C = \frac{15.328\,L}{88{,}900\,A R_{20}} \quad \text{per cent.}$$

Annealed or soft-drawn copper usually has a conductivity of 100 per cent, hard-drawn copper a conductivity of about 97 per cent. Ordinary hard-drawn aluminum has a conductivity of 61 per cent. The conductivity of iron or steel wire ranges from 8 to 16 per cent.

DIMENSIONS, RESISTANCE AND WEIGHT. — The following tables for copper and aluminum are compiled from the tables in *Circular No. 31 of the Bureau of Standards (1914 ed.)*, except that for stranded aluminum on p. 1868.. The table for steel wire is compiled from that published by the American Steel and Wire Co., and the table for copper-clad steel wire is based on data published by the Duplex Metals Co.

*Let C = per cent conductivity, R_{20} = resistance of 61 per cent conductivity wire at 20° C. (from table), R_t = resistance of wire of conductivity C at any temperature t° C., then

$$R_t = \frac{61\ R_{20}}{C}[1 + 0.004\ (t - 20)].$$

ALUMINUM CABLES.

The commercial sizes of stranded aluminum cables, made by the Aluminum Company of America, are not even circular mil and B. & S. sizes, but are of such cross sections as to give the same conductivity as even circular mil and B. & S. sizes of copper cables of 97 per cent conductivity. In the following table the first four and the seventh columns are taken from a pamphlet entitled "Instructions for Installation and Maintenance of Aluminum Electrical Conductors," issued by the Aluminum Company of America, in 1914.

B. & S. gage or circular mils		Usual number of strands	Diameter of bare cable, inches	Resistance at 25° C. or 77° F.*		Weight in pounds	
Copper (97 per cent) equivalent	Aluminum 61 per cent			Ohms per 1000 feet	Ohms per mile	per 1000 feet	per mile

*Let C = per cent conductivity,
R_{20} = resistance of 12.5 per cent conductivity wire at 20° C. (from table),
R_t = resistance of wire of any conductivity C at any temperature t° C.,
then

$$R_t = \frac{12.5\,R_{20}}{C}[1 + 0.006\,(t - 20)].$$

The temperature coefficient is approximate only.

Copper-clad Steel Wire.—This wire consists of a steel core and a concentric coat of copper permanently welded thereto. It is used chiefly for long span transmission and telephone wire. It is made in several grades, which differ in the relative amounts of steel and copper. The grades are designated by the corresponding conductivity expressed as per cents of Matthiessen's Standard; e.g., 40 per cent grade has a conductivity of 40 per cent.

* Let C = per cent conductivity,
$R_{23.9}$ = resistance of 40 per cent conductivity wire at 23.9° C. (from table),
R_t = resistance of wire of conductivity C at temperature t° C.,

then

$$R_t = \frac{40\, R_{23.9}}{C}\,[1 + 0.00432\,(t - 23.9)].$$

The temperature coefficient is approximate only.

Alloy Wires of High Tensile Strength.—Copper alloys having a low conductivity, but having a tensile strength from 50 per cent to 100 per cent greater than that of copper are sometimes used where strength or hardness is a primary requisite, as in long spans of small wires or for trolley wires. The Bridgeport Brass Co. make a wire known as "phono-electric wire" which has a conductivity of 25 per cent and a tensile strength ranging from 68,000 pounds per square inch for No. 0000 B. & S. gauge to 85,000 pounds per square inch for No. 18 B. & S. gage.

Trolley Wire. — Trolley wires of two different sections are in use in the United States. The sections shown in Fig. 1 are known as the "American Standard" and the sections shown in Fig. 2 as the "Figure 8" sections. The

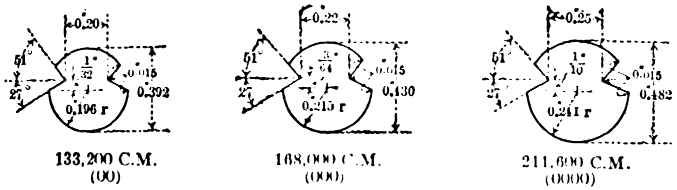

Fig. 1. American Standard Trolley-wire Sections

American Society for Testing Materials recommend that the sizes be specified in circular mils, and not as gage numbers; the sizes shown in the figure differ in the area of the cross-section from the gage numbers given in parentheses by less than 5 parts in 1000.

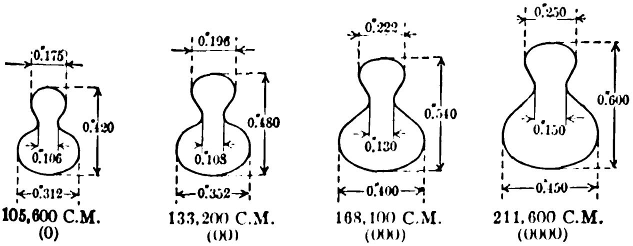

Fig. 2. "Figure 8" Trolley-wire Sections

Trolley wires are usually of hard-drawn copper; the electrical and mechanical properties are the same as for round hard-drawn wire of the same cross-section. Copper alloys, such as phono-electric wire (*see above*), are sometimes used for trolley wires.

FACTORS AFFECTING DIMENSIONS, WEIGHT AND RESISTANCE OF STRANDED WIRES. — Individual stranded wires or cables are of four different types, namely: (a) bunched wire; (b) wire braids; (c) concentric-lay cables and (d) rope-lay cables.

Bunched Wires. — Bunched wires are used especially for those extra flexible cables known as cords, wherein the individual wires are so small that concentric stranding is not necessary to keep them together. The wires are assembled parallel and then generally given a slight twist. Sometimes they are kept together by being wound with soft cotton thread which also serves to prevent adhesion between the insulation and wires.

Wire Braids. — In the flat form, wire braids are used for potential leads, etc., in lighting cables, where a flexible flat conductor is necessary. Tubular wire braids are also frequently formed over the insulation of cables in order to afford mechanical protection. Cables for naval or military purposes and for automobile work are frequently thus protected.

Concentric-lay Cables. — A concentric-lay cable is a stranded conductor composed of a central core surrounded by one or more layers of helically laid

wires. A rope-lay cable is a stranded wire made up in the same manner by using stranded wires instead of individual solid wires for the core and layers. The cores of concentric-lay cables may be composed of one, two, three or four wires of equal diameter. A five or six wire core would not be symmetrical and seven wires would themselves constitute a core and a layer.

Number of Wires in Concentric-lay Cables. — Hence the following table gives all the possible concentric-lay cables with eight or less layers of equal size wires and formulæ for calculating the number of wires with any number of layers.

NUMBER OF WIRES IN CONCENTRIC-LAY CABLES

(All wires of same diameter)

Number of layers over core	Number of wires in core			
	1	2	3	4
0	1	2	3	4
1	7	10	12	14
2	19	24	27	30
3	37	44	48	52
4	61	70	75	80
5	91	102	108	114
6	127	140	147	154
7	169	184	192	200
8	217	234	243	252
n	$3n^2+3n+1$	$3n^2+5n+2$	$3n^2+6n+3$	$3n^2+7n+4$

The number of wires per layer increases by six for each successive layer when the core has one wire, the first layer over the core having six. With cores having more than one wire, the increment per layer is not constant.

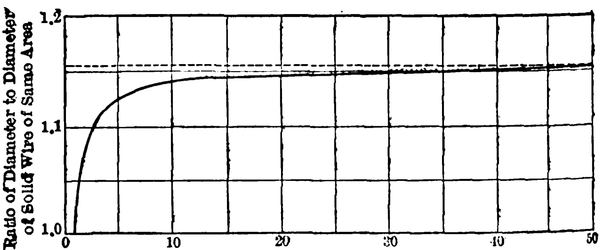

Fig. 3.

Diameter of Concentric-lay Cables. — The diameter of the circumscribing circle of any of the above cables is equal to $(2n + b)$ times the diameter of each wire, where n is the number of layers over the core and b has the following values: 1 wire in core, $b = 1$; 2 wires in core, $b = 2$; 3 wires in core, $b = 2.155$; 4 wires in core, $b = 2.414$.

The relation between the number of component wires and the diameter of the cable is shown in Fig. 3.

COMMERCIAL STRANDED CONDUCTORS

Weights in lb. per 1000 ft. of all bare copper cables are computed by multiplying the circular mils by 0.00309.

Rope-lay Cables. — As already noted, a rope-lay cable is made up in the same way as a concentric-lay cable except that stranded wires are used for the core and layers instead of individual solid wires. Rope strands are used for large conductors which would be too stiff if stranded concentrically. The formulas for regular concentric-lay cables may be readily modified to apply to rope-lay cables, as each stranded wire bears the same relation to the rope as each individual solid wire does to the concentric-lay cable. The following table gives the principal forms of rope-lay cables.

WIRES IN ROPE-LAY CABLES

Number of layers over core	Number of strands*	Total number of wires				
		Wires per strand*				
		7	19	37	61	91
0	1	7	19	37	61	91
1	7	49	133	259	427	637
2	19	133	361	703	1159	1,729
3	37	259	703	1369	2257	3,367
4	61	427	1159	2257	3721	5,551
5	91	637	1729	3367	5551	8,281
6	127	889	2413	4699	7747	11,557
n	$3(n^2+n)+1$	$21(n^2+n)+7$	$57(n^2+n)+19$	$111(n^2+n)+37$	$183(n^2+n)+61$	$273(n^2+n)+91$

* By "strand" is here meant the stranded wires of which the rope is built up.

The number of wires in a rope-lay cable is frequently designated by a product; thus, 7×19 indicates a conductor made up of 7 strands, each strand containing 19 wires.

Hemp-core Cables. — Cables with hemp centers have caused serious trouble and are not being recommended. (D. B. Rushmore, *G. E. Review, June, 1912.*)

Diameters of Component Wires in Commercial Stranded Conductors. — The table on p. 1875 gives the diameters of the component wires in the types of stranded conductors ordinarily used.

Effect of Lay on Resistance and Weight. — In the tables given on pp. 1860, 1862 and 1868, for stranded cables, the values given for "ohms per unit length" and "weight per unit length" are 2 per cent greater than for a solid rod of cross-section equal to the total cross-section of the wires of the cable. This increment of 2 per cent means that the values are correct for cables having a lay of 1 in 15.7. For any other lay, equal to 1 in n, resistance or mass may be calculated by increasing the above tabulated values by

$$\left(\frac{484}{n^2} - 2\right) \text{ per cent.}$$

General Formulas for Properties of Cables in Terms of the Properties of the Constituent Wires. — The following table gives the principal formulas for concentric-lay cable having a core of one wire.

A = total area in circular mils of the component wires measured at right angles to their axes, when laid out straight.

D = diameter of cable over-all, in inches.

d = diameter of each of the component wires, in inches.

d = diameter of core, in inches.

d_p = pitch diameter, in inches, of any layer (= mean diameter of the helix made by any layer).
e = elongation, per cent, at which the wires (other than the core) break.
l = number of wires in any layer having pitch diameter d_p.
N = total number of wires except where the core is of special size, in which case N is the number of wires exclusive of the core.
n = number of layers of wire over the core.
P = pitch of any layer of wires = distance in inches measured along the axis of the cable for one complete turn of the helix formed by any wire of this layer.
p = pitch-factor of any layer of wires = ratio of the actual length of a wire to the corresponding axial length of the cable.
R = ratio of wire area to the total area of the circle circumscribing the outside of the conductor.
s = stress in pounds per square inch in the core when the elongation is e.
t = tensile strength of each outer wire, in pounds per square inch.
T = tensile strength of conductor, in pounds.
W = weight of conductor, in pounds per foot.
w = weight of each wire of the cable, in pounds per foot.
w_c = weight of the core of the cable, in pounds per foot.

PROPERTIES OF CONCENTRIC-LAY CABLES

		Regular; $d_c = d$	Special; $d_c \neq d$
I.	Number of wires in terms of number of layers (and core diameter).	$N = 3(n^2+n)+1$ (including core)	$N = 3\left(n\frac{d_c}{d}+n^2\right)$ (excluding core)
II.	Diameter of cable in terms of diameter of wires and number of layers.	$D = d(1+2n)$	$D = d_c + 2nd$
III.	Diameter of cable in terms of total area and number of wires.	$D = 10^{-3}\sqrt{\frac{1}{3}\left(4-\frac{1}{N}\right)}\cdot\sqrt{A}$	
IV.	Ratio of wire area to area of circle circumscribing the outside of cable.	$R = \frac{3(n^2+n)+1}{(2n+1)^2}$	
V.	Weight of cable in terms of weight of wire, number of layers and pitch factors.	$W = w(1+6p_6+12p_{12}+\text{etc.})$	$W = w_c + w(1+6p_6+12p_{12}+\text{etc.})$
VI.	Strength of cable in terms of strength of the component wires and the pitch factors.	$T = \frac{\pi}{4}d^2\left[s+t\left(\frac{6}{p_6}+\frac{12}{p_{12}}+\text{etc.}\right)\right]$	$T = \frac{\pi}{4}\left[sd_c^2+d^2t\left(\frac{6}{p_6}+\frac{12}{p_{12}}+\text{etc.}\right)\right]$

PROPERTIES OF CONCENTRIC-LAY CABLES—*Continued*

		Regular; $d_o = d$	Special; $d_o \neq d$
VII.	Minimum pitch in terms of wire diameter and core diameter.	$\frac{3\pi d_p}{\sqrt{(\pi+3)(\pi-3)}} = 10.1$ times pitch diameter	$\frac{\pi d_p l d}{\sqrt{(\pi d_p)^2-(ld)^2}}$
VIII.	Diameter of wires in terms of total conductor area and number of wires.	$d = \frac{1}{1000}\sqrt{\frac{A}{N}}$	

STRENGTH, ELASTICITY AND EXPANSION COEFFICIENT OF WIRES.—The strength and elasticity of a wire of any material depends to a considerable extent upon the method of manufacture, heat treatment, etc. The tensile strength of soft copper is between 25,000 and 35,000 pounds per square inch, as against 60,000 pounds per square inch for hard-drawn copper. Again, due to the greater relative thickness of the hard "skin" and comparatively soft "core" of small hard-drawn copper wires as compared with large wires, the tensile strength, in pounds per square inch, of a small hard-drawn copper wire is greater than the tensile strength of a large hard-drawn wire. For example, a No. 0000 B. & S. hard-drawn copper wire has a tensile strength of about 50,000 pounds per square inch as against approximately 65,000 pounds per square inch for a No. 18. A similar but smaller variation holds for soft-drawn wires. The tensile strength of steel wire depends to a very great extent upon the composition of the steel.

The following table gives, for a No. 0 A. W. G. wire, representative values of the various quantities stated. These values do not hold, except to a rough approximation, for other sizes of wire. For further information see articles on *Copper*, *Aluminum*, etc., and the section on *Specifications* below.

STRENGTH, ELASTICITY AND COEFFICIENT OF EXPANSION
Of a No. 0 A. W. G. or B. & S. Wire

Kind of wire	Tensile strength, lb. per sq. in.	Elastic limit, lb. per sq. in.*	Modulus of elasticity, lb.-in. units	Coefficient of linear expansion per °F.	Coefficient of linear expansion per °C.
Copper, soft-drawn	36,000	......	....	9.6×10^{-6}	17×10^{-6}
Copper, hard-drawn	54,500	30,000	16×10^6	9.6×10^{-6}	17×10^{-6}
Aluminum, soft-drawn	16,000	......	....	12.8×10^{-6}	23×10^{-6}
Aluminum, hard-drawn	25,000	25,000	9×10^6	12.8×10^{-6}	23×10^{-6}
Copper-clad steel, 40% grade	60,000	51,000	22×10^6	6.7×10^{-6}	12×10^{-6}
Phono-electric	75,800	55,000	18×10^6	8.3×10^{-6}	14.9×10^{-6}
Steel, ordinary	68,000	40,000	24×10^6 to 30×10^6	7.0×10^{-6}	12.6×10^{-6}
Steel, Siemens-Martin	90,000	45,000		7.0×10^{-6}	12.6×10^{-6}
Steel, high strength	150,000	82,000		7.0×10^{-6}	12.6×10^{-6}
Steel, extra high strength	225,000	135,000		7.0×10^{-6}	12.6×10^{-6}

* There is no elastic limit for soft annealed copper and the elastic limits of hard-drawn copper and aluminum are doubtful.

The tensile strength in pounds for solid wires from 1/16 inch to 1/2 inch in diameter are given in the following table.

BREAKING LOAD FOR SOLID WIRES IN POUNDS PER WIRE

Gage No. A.W.G. or B. & S.	Diameter		Hard-drawn copper (Am. Soc. for Test. Mat.)*	Hard-drawn aluminum (23,000 to 33,300 lb. per sq. in.)	Copper-clad steel, 40 per cent grade (Duplex Metals Co.)	Steel (100,000 lb. per sq. in.) †
	Inches	Mils				
	1/2	500	9310	4520	11,400	19,640
0000		460	8140	3820	10,000	16,620

	1/16	62	203	98	310	307

* Tensile strength in pounds per square inch ranging from 49,000 for No. 0000 to 66,200 for No. 14; see below.

† For wires having a tensile strength of S pounds per square inch, multiply by $S/100{,}000$. The tensile strength of steel varies from 60,000 to 225,000 pounds per square inch.

Strength, Elasticity and Expansion Coefficient of Cables.—The following is a summary of the results of tests made on stranded copper wires at the Massachusetts Institute of Technology in 1912. Each figure is the average of a number of individual tests. In determining the modulus of elasticity each cable was given a preliminary stretch before readings were taken.

MECHANICAL PROPERTIES OF BARE COPPER CABLES

Designation	Size of cable A. W. G. and cir. mils	Number of wires in cable	Pitch of layers, inches		Modulus, lb.-in. units	Elastic limit, lb. per sq. in.	Tensile strength, lb. per sq. in.
			First layer	Second layer			
A	0	7	4.5	...	16.6×10^6	22,000	53,500
B	300,000	19	7	5	16.4×10^6	21,300	59,800
C	300,000	19	9	4.5	16.3×10^6	25,000	56,000
D	300,000	19	9	9	16.5×10^6	24,000	52,600
E	300,000	19	4.5	3	13.6×10^6	25,300	53,800

PROPERTIES OF COMPONENT WIRES OF ABOVE CABLES

Wires from cable	Size of component wires, mils	Modulus, lb.-in. units	Elastic limit, lb. per sq. in.	Tensile strength, lb. per sq. in.
B	125	16.9×10^6	27,000	62,800
C	125	18.9×10^6	27,000	61,900
D	125	16.6×10^6	26,000	61,800
E	125	17.5×10^6	26,000	59,300

No data are available on the expansion coefficient of stranded wires, but it seems reasonable to assume that it would be approximately the same for stranded as for solid wires.

Steel Cable for Catenary Construction.— In the report of the Committee on Power Distribution of the American Street and Interurban Ry. Assoc., 1908, a modulus of 22×10^6 pound-inch units is given as representative of ordinary steel messenger cable.

The following tables are compiled from tables published by the General Electric Co. (*Bulletin 4538, 1907*). "High" and "Extra high" strength steel should only be used where absolutely necessary, as, on account of its stiffness, it requires special mechanical fastenings.

STEEL CABLE FOR CATENARY SUSPENSION

Extra-galvanized Siemens-Martin Steel Strand, 90,000 Pounds Per Square Inch.				
Diameter, inches	Tensile strength, pounds	Elastic limit, pounds	Elongation, per cent	Lay, inches
1/4	3,060	1,830	6 to 9	3
5/16	4,860	2,910	6 to 9	3 1/2
3/8	6,800	4,080	5 to 8	4
7/16	9,000	5,300	5 to 8	4 1/2
1/2	11,000	6,600	5 to 8	4 1/2
5/8	19,000	11,400	4 to 6	5

STEEL CABLE FOR CATENARY SUSPENSION — (*Continued*)

Extra-galvanized High-strength Crucible Steel Strand

⅝	42,000	31,500	1½ to 3	6

COMPARISON OF COPPER AND ALUMINUM FOR EQUAL LENGTH AND EQUAL RESISTANCE. — (*See Aluminum.*)

CURRENT-CARRYING CAPACITY OF BARE WIRES. — (*See also articles on Rheostats; Wires, Resistance.*) Let d = diameter of conductor in inches, T = permissible temperature rise in ° C. above surrounding medium (air, earth, or water), r = resistance of conductor in ohms per mil foot at final temperature, I = current per conductor in amperes. Assuming that the rate of heat radiation per unit length of wire is proportional to the difference of temperature between the conductor and the surrounding medium and also proportional to the surface of the conductor, then for solid conductors

$$I = K\sqrt{\frac{Td^3}{r}},$$

and for stranded conductors

$$I = 0.85\,K\sqrt{\frac{Td^3}{r}},$$

where K is a constant, which depends upon the condition of the surface of the wire, and upon the amount of heat convection due to air currents. Values of the constant K for air given by different authorities vary from 800 to 1000, the former referring to still air and the latter to open air.

TESTS OF BARE WIRES AND CABLES. — The usual tests on bare wires are gaging diameter, measuring tensile strength, elongation, modulus, elastic limit and electrical conductivity. These tests are:

Gaging Diameter. — (*See also section on Specifications, below.*) The best type of gage for measuring wire diameters is that shown in Fig. 4. The wire is placed between the measuring surfaces and the screw adjusted until a click occurs. The number of large divisions exposed on the axis is multiplied by 100; the number of small divisions exposed on the axis is multiplied by 25; and the sum of these two items added to the number indicated on the revolving scale. The sum will be the diameter of the wire in mils.

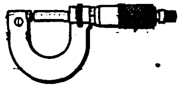

Fig. 4.

Tensile Strength, Elongation, Modulus and Elastic Limit. — The essential features of a wire-testing machine are a means of applying a measurable pulling force to the wire, and a means of taking up the elongation. Accordingly, the usual testing machine consists of two pairs of jaws for gripping the wire, one pair being connected to a balance lever and the other pair to a power-driven mechanism which draws it in the direction of the axis of the wire. A typical machine is shown diagrammatically in Fig. 5, where *A* and *B* are the two pairs of jaws between which the wire is stretched. The machine is operated by setting in motion the mechanism which makes the jaw *A* move steadily in the direction indicated. The operator then moves the counterpoise *C* by hand, in the direction indicated, so as to keep the beam balanced. This operation is continued until the wire breaks, when the elongation of the sample is measured by the travel of the jaw *A* and its breaking strength by the weight indicated on the balance beam at the counterpoise *C*.

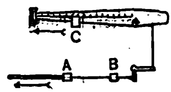

Fig. 5.

Measurement of Strain. — The amount by which the wire is stretched is measured by means of an extensometer which consists of a pair of clamps to grip the wire at points a definite distance apart, and a magnifying scale for measuring the increase of distance between these clamps as the wire stretches. The stress-strain curve obtained by plotting the elongations thus measured against the stresses measured by the machine described above is not a true one, as there is initially an abnormal elongation due to the straightening of the wire. It is, therefore, necessary to plot an initial curve as shown by *A* in Fig. 6, then to continue the line of true linear extension backward and replot the curve so that the exterpolated line passes through zero.

Modulus of Elasticity. — The modulus of elasticity is obtained from the slope of the straight part of the redrawn curve. In Fig. 6 the modulus of elasticity is *OD/CD* pound-inch units.

Elastic Limit. — The true elastic limit can be obtained only by applying a series of increasing loads, releasing the load (leaving, however, a sufficient load to keep the wire straight) and measuring the elongation between successive loads. The load at which a permanent elongation begins is the elastic limit.

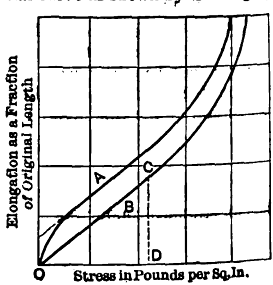

Fig. 6.

Conductivity. — In order to maintain a wire at a uniform and known temperature, it must be short. Unless the wire is very small the test sample will

therefore have a very low resistance, and an ordinary Wheatstone bridge will not be sufficiently accurate to measure it. This difficulty is avoided by using a bridge of either the Kelvin, Hoop, Willyoung or Reeves type (*see Bridges for Electrical Measurements; Resistance and Conductance*).

SPECIFICATION FOR SOFT OR ANNEALED COPPER WIRE. — The following specifications for bare copper wire are those prepared by the American Society for Testing Materials, August 21, 1911 (hard-drawn copper), and June 1, 1912 (soft-drawn copper). See also the article on *Specifications and Contracts*, and the section on *Specifications* in the article on *Wires and Cables, Insulated.*

1. **General.** — The copper shall be of such quality and purity that, when drawn and annealed, it shall have the properties and characteristics herein required.

2. This specification covers untinned, drawn and annealed round wire.

3. (*a*) The wire must be free from all surface imperfections not consistent with the best commercial practice.

(*b*) Necessary brazes in soft or annealed wire must be made in accordance with the best commercial practice.

4. **Shipment; Coils, Spools and Reels.** — (*a*) Wire may be shipped in coils or on reels as agreed upon by the purchaser and manufacturer. In Table I (*below*) there are stated the maximum and minimum weights of wire of the stated sizes which may be shipped in any one package, whether coil, reel or spool; in the case of wire larger than 0.010 inch in diameter, the maximum and minimum package weights are net, and in the case of wire 0.010 inch and less in diameter, the maximum package weights are gross, and the minimum package weights are net. The table also states the limiting of the dimensions of the coils, reels and spools on which wire may be shipped. The length and diameter stated for reels and spools are to be measured over-all and are maximum sizes; reels or spools smaller than these may be used provided the minimum weights called for are carried by the reel or spool. In the table, there are also stated the diameters of the draw-block on which the final drawing of the wire is to be made, when wire is shipped in coils; it being understood that the wire is not to be rewound after final drawing. This provision is made to insure that coils of wire of a given gauge, when supplied by different manufacturers, will be of the same general dimensions.

Wire 0.204 inch in diameter and larger may be shipped in larger packages when agreed upon.

(*b*) The wire shall be protected against damage in ordinary handling and shipping.

5. **Specific Gravity.** — For the purpose of calculating weights, cross-sections, etc., the specific gravity of copper shall be taken as 8.90.

6. **Size and Gaging.** — (*a*) Size shall be expressed as the diameter of the wire in decimal fractions of an inch.

(*b*) Wire shall be accurate in diameter; permissible variations from nominal diameter shall be:

For wire 0.010 inch in diameter and larger, 1 per cent over or under.

For wire less than 0.010 inch in diameter, 0.1 mil (0.0001 inch) over or under.

(*c*) Each coil shall be gaged at three places, one near each end and one approximately at the middle; from spools, approximately twelve feet shall be reeled off, the wire shall be gaged in six places between the second and twelfth foot from the end. The coils or spools will be rejected if the average of the measurements obtained is not within the limits in (*b*).

TABLE I

Diameters, inches	Package weights, pounds		Diam. of draw-block, inches	Dimensions of reels and spools, inches		
	Max.	Min.		Max. diam.	Max. length	Diameter of hole for rod
0.460 to 0.360	520	290	24	32	21	1½ to 2½
0.359 to 0.258	430	290	24	32	21	1½ to 2½
0.257 to 0.129	290	140	22	24	12	1½ to 2½
0.128 to 0.102	230	95	22	24	12	⅝ to 1½
0.101 to 0.083	230	75	22	24	12	⅝ to 1½
0.082 to 0.081	200	75	16	24	12	⅝ to 1½
0.080 to 0.064	200	50	16	24	12	⅝ to 1½
0.063 to 0.051	120	50	16	24	10	⅝ to 1½
0.050 to 0.041	100	50	16	24	10	⅝ to 1½
0.040 to 0.032	50	20	8	24	8	⅝ to 1⅛
0.031 to 0.020	25	15	8	10	6½	⅝ to ⅞
0.019 to 0.011	10	5	8	5½	4	⅜ to 1 1/16
0.010 to 0.008	5	2½	8	4	4	⅜ to 1 1/16
0.007 to 0.0056	2½	1	6	2½	4	⅜ to 1 1/16
0.005	1½	⅝	6	2½	4	⅜ to 1 1/16
0.004	1½	⅜	6	2½	4	⅜ to 1 1/16
0.003	1	¼	6	2½	4	⅜ to 1 1/16

7. **Tensile Strength and Elongation.**—Wire shall be so drawn and annealed that its tensile strength shall not be greater and its elongation not less than the values stated in Table II. Tensile tests shall be made upon fair samples, and the elongation shall be determined as the permanent increase in length, due to the breaking of the wire in tension, measured between bench marks placed upon the wire originally 10 inches apart. The fracture shall be between the bench marks and not closer than 1 inch to either bench mark. If, upon testing a sample from any coil, reel or spool of wire, the results are found to be below the stated value in elongation or above the stated value in tensile strength, tests upon two additional samples shall be made, and the average of the three tests shall determine acceptance or rejection of the coil. For wire whose nominal diameter is between listed sizes, the requirements shall be those of the next larger size included in the table.

TABLE II.—ANNEALED COPPER WIRE

Diameter, inches	Tensile strength, lb. per sq. in.	Elongation in 10 in., per cent
0.460–0.290	36,000	35
0.289–0.103	37,000	30
0.102–0.021	38,500	25
0.020–0.003	40,000	20

8. **Conductivity.** — Electric conductivity shall be determined upon fair samples by resistance measurements at a temperature of 20° C. (68° F.) and it shall not exceed 891.58 pounds per mile-ohm.

9. **Testing and Inspection.** — All testing and inspection shall be made at the place of manufacture. The manufacturer shall afford the inspector representing the purchaser all reasonable facilities to satisfy him that the material conforms to the requirements of these specifications.

SPECIFICATION FOR HARD-DRAWN COPPER WIRE.

1. **General.** — The material shall be copper of such quality and purity that, when drawn hard, it shall have the properties and characteristics herein required. (*See § 1 of preceding specification.*)

2. This specification covers hard-drawn round wire, grooved trolley wire, figure-eight trolley wire, and hard-drawn cable or strand, as hereinafter described.

3. (*a*) The wire, in all shapes, must be free from all surface imperfections not consistent with the best commercial practice.

(*b*) Necessary brazes in hard-drawn wire must be made in accordance with best commercial practice, and tests upon a section of wire containing a braze must show at least 95 per cent of the tensile strength of the unbrazed wire. Elongation tests are not to be made upon test sections including brazes.

4. **Shipment.** — (*a*) Package sizes for round wire and for cable shall be agreed upon in the placing of individual orders; standard packages of grooved trolley wire shall be shipped upon reels holding about 2500 pounds each.

(*b*) The wire shall be protected against damage in ordinary handling and shipping.

5. **Specific Gravity.** — For the purpose of calculating weights, cross-sections, etc., the specific gravity of copper shall be taken as 8.90.

6. **Testing and Inspection.** — All testing and inspection shall be made at the place of manufacture. The manufacturer shall afford the inspector representing the purchaser all reasonable facilities to enable him to satisfy himself that the material conforms to the requirements of these specifications.

7. **Size and Gaging of Round Wire.** — (*a*) Size shall be expressed as the diameter of the wire in decimal fractions of an inch, using not more than three places of decimals; i.e., in mils.

(*b*) Wire is expected to be accurate in diameter; permissible variations from nominal diameter shall be:

For wire 0.100 inch in diameter and larger, one per cent over or under;
For wire less than 0.100 inch in diameter, one mil over or under.

(*c*) Each coil is to be gaged at three places, one near each end, and one approximately at the middle; the coil may be rejected if, two points being within the accepted limits, the third point is off gage more than 2 per cent in the case of wire 0.064 inch in diameter and larger, or more than 3 per cent in the case of wire less than 0.064 inch in diameter.

8. **Tensile Strength and Elongation of Round Wire.** — Wire shall be so drawn that its tensile strength and elongation shall be at least equal to the value stated in Table III. Tensile tests shall be made upon fair samples, and the elongation of wire larger in diameter than 0.204 inch shall be determined as the permanent increase in length, due to the breaking of the wire in tension, measured between bench marks placed upon the wire originally 10 inches apart. The elongation of wire 0.204 inch in diameter and smaller shall be determined by measurements made between the jaws of the testing machine. The zero length shall be the distance between the jaws when a load equal to 10 per cent of the required ultimate breaking strength shall have been applied, and the

final length shall be the distance between the jaws at the time of rupture. The zero length shall be as near 60 inches as possible. The fracture shall be between the bench marks in the case of wire larger than 0.204 inch in diameter and between the jaws in the case of smaller wire, and not closer than 1 inch to either bench mark or jaw. If, upon testing a sample from any coil of wire, the results are found to be below the values stated in the table, tests upon two additional samples shall be made, and the average of the three tests shall determine acceptance or rejection of the coil. For wire whose nominal diameter is between listed sizes, the requirements shall be those of the next larger size included in the table.

TABLE III.—HARD-DRAWN COPPER WIRE

Approx. Gage No., B. & S.	Diameter, inches	Area, circular mils	Tensile strength, lb. per sq. in.	Elongation, per cent
				in 10 in.
0000	0.460	211,600	49,000	3.75
000	0.410	168,100	51,000	3.25
00	0.365	133,225	52,800	2.80
0	0.325	105,625	54,500	2.40
1	0.289	83,520	56,100	2.17
2	0.258	66,565	57,600	1.98
3	0.229	52,440	59,000	1.79
				in 60 in.

	0.165	27,225	62,000	1.14
6	0.162	26,245	62,100	1.14
7	0.144	20,735	63,000	1.09
	0.134	17,956	63,400	1.07
8	0.128	16,385	63,700	1.06
9	0.114	12,995	64,300	1.02
	0.104	10,815	64,800	1.00
10	0.102	10,404	64,900	1.00
	0.092	8,464	65,400	0.97
11	0.091	8,281	65,400	0.97
12	0.081	6,561	65,700	0.95
	0.080	6,400	65,700	0.94
13	0.072	5,184	65,900	0.92
	0.065	4,225	66,200	0.91
14	0.064	4,096	66,200	0.90
15	0.057	3,249	66,400	0.89
	0.051	2,601	66,600	0.87
16	0.045	2,025	66,800	0.86
18	0.040	1,600	67,000	0.85

9. **Conductivity of Round Wire.**—Electric conductivity shall be determined upon fair samples by resistance measurements at a temperature of 20° C. (68° F.).

The wire shall not exceed the following limits:

For diameters 0.460 inch to 0.325 inch, 900.77 pounds per mile-ohm at 20° C.

For diameters 0.324 inch to 0.040 inch, 910.15 pounds per mile-ohm at 20° C.

10. **Grooved Trolley Wire.** — Standard sections shall be those known as the "American Standard" grooved trolley-wire sections, the shape and dimensions of which are as shown in Fig. 1, above.

11. (*a*) Size shall be expressed as the area of cross-section in circular mils, the standard sizes being as follows:

211,600 circular mils, weighing 3386 pounds per mile.
168,100 circular mils, weighing 2690 pounds per mile.
133,200 circular mils, weighing 2132 pounds per mile.

(*b*) Grooved trolley wire may vary 4 per cent over or under in weight per unit length from standard, as determined from the nominal cross-section.

12. The physical tests shall be made in the same manner as those upon round wire. The tensile strength of grooved wire shall be at least 95 per cent of that required for round wire of the same sectional area; the elongation shall be the same as that required for round wire of the same sectional area.

13. The requirements for electric conductivity shall be the same as those for round wire of the same sectional area.

14. **Figure-eight Trolley Wire.** — Standard sections of figure-eight trolley wire shall be as shown in Fig. 2, above.

15. The requirements for weight, physical properties and electric conductivity of figure-eight trolley wire shall be the same as for the same sizes of grooved trolley wire.

16. **Hard-drawn Copper Wire Cable or Strand.** — For the purposes of these specifications, standard cable shall be that made up of hard-drawn wire laid concentrically about a hard-drawn wire center. Cable laid up about a hemp center or about a soft-wire core is to be subject to special specifications to be agreed upon in individual cases.

17. The wire entering into the construction of stranded cable shall, before stranding, meet all the requirements of round wire, hereinbefore stated.

18. The tensile strength of standard cable shall be at least 90 per cent of the total strength required of the wires forming the cable.

19. Brazes, made in accordance with the best commercial practice, will be permitted in wire entering into cable; but no two brazes in wire in the cable may be closer together than 50 feet.

20. The pitch of standard cable shall not be less than 12, nor more than 16, diameters of the cable. The cable shall be laid left-handed or right-handed, as shall be agreed upon in the placing of individual orders.

Extract from Notes to Above Specifications. — The permitting of brazes in wire entering into the construction of copper cable was discussed at considerable length, and it is finally the opinion of the Committee that, provided no two brazes are closer together than 50 feet, the cable has fully 90 per cent of the theoretical strength obtained by adding together the required strengths of the constituent wires. This is due, in such long lengths, to the frictional gripping of the wires in the cable. The construction of long lengths of cable without brazes is costly, and it has been thought best, therefore, to permit their use, provided they are sufficiently widely spaced as not to be detrimental to the strength of the cable.

INSTALLATION OF BARE WIRES AND CABLES. — For the installation of wires and cables in buildings see article on *Wiring of Buildings for Light and Power*. Below is given a brief description of modern practice in erecting bare wires and cables on pole or tower lines. For the construction of the latter see articles on *Distribution Lines; Transmission Lines*. Catenary construction is described in the article on *Trolley Systems, Overhead*.

Simple Span Construction with Pin Insulators. — Starting at an anchored pole, a rope about twice the length of the span is put over the cross arm and the wire pulled up by means of it. The rope is then put over the cross arm of the next pole and the wire drawn up in the same way. This is repeated from pole to pole until the reel, which remains at the starting point, is exhausted. The pulling may be done by men, horses, automobile, or locomotive. Care should be taken to prevent the wire unwinding too rapidly from the reel and the end of the wire must be prevented from slipping away.

The wire is placed on the insulators by means of a block and tackle attached either to the arm above or to a temporary boom. The next step is to draw the wires to the proper tension. Commencing at the first pole after the anchorage, the wire is gripped by a clamp attached to a rope which is pulled until the wire is drawn to the sag indicated by a table or curve showing the proper sag for different temperatures and spans (*Spans, Wire*). The sag is gauged by sighting from pole to pole, using a gauge or sight on each pole, and drawing the wire until the bottom of the span is tangential to the sight line.

Tying to Insulator.— (*See also Insulators for Overhead Lines.*) The wires are tied to their insulators by small wires, usually of the same metal, as shown in Fig. 7. The two ends of the tie wire (not visible in Fig. 7) are twisted together for three or four turns. The tie wire must be held quite taut while it is being installed.

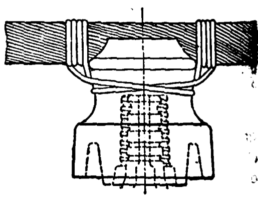

Fig. 7.

Simple Span Construction with Suspension Insulators. — Where suspension insulators are used, the wire, instead of being initially placed over the cross arms, is temporarily suspended therefrom on snatch blocks provided with wooden rollers. Prior to running the cables, linemen are sent ahead to attach the snatch blocks to the arms of the towers. The cables are then strung loosely through the snatch blocks, in much the same way as they are strung over the cross arms in the construction described above. The cables are anchored to the first pole and the necessary tension applied to the cable between the first and second towers, a dynamometer being used to indicate when the required stress point has been reached. The cable is then anchored to the second tower and the operation repeated for the different spans until the cable length is exhausted. The cable is then transferred to the insulator clamps and the anchorages removed except at the ends.

Clamping to Insulator. — The usual type of insulator clamp (Fig. 8) consists of a curved, malleable-iron wire seat about nine inches long, a saddle which fits over the wire and a pair of hook bolts to hold the wire tightly between the saddle and wire seat. The wire seat is supported from the insulator through a swivel joint. Copper wire or cable is laid in the wire seat, the saddle placed on it and the hook bolts placed in position. In the case of aluminum wire a 1/16-inch aluminum sleeve should be placed around the wire in the clamp. The entire clamp is then attached to the insulator by a bolt and socket or pin joint.

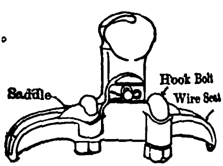

Fig. 8.

Jointing Conductors. — The following methods are used:

Western Union Joint. — The two ends of the wire are brought together so that they lap from 3 to 8 inches, depending upon the size. Then

beginning half-way between the two ends, each wire is wound around the other wire in a tight helix. With hard-drawn copper, excessive stress is avoided by giving the helix a long pitch for the first turn or two and then gradually reducing the pitch until a tight helix is obtained.

It would appear from tests on galvanized-iron wire by C. T. Rashman (*E. W., 1910, Vol. 56, p. 1187*), that in order to make the joint as strong as the wire, it should have the form shown in Fig. 9 which may be described as consisting of a neck of five turns and five end turns at each end.

Fig. 9.

Fig. 10.

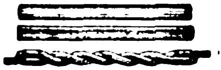

Fig. 11.

In order to obtain five turns in the neck, the following length of neck was found necessary:

Size wire, B.W.G.	Length of neck, inches
14	3-1/2
12	3-3/4
10	4
8	6
6	7

The form of splice shown in Fig. 10 should be avoided.

Dovetailing Strands. — The cables are unwound for say three or four feet, dovetailed or interlaced, and the strands individually wound round the unopened part of the cable. The joint may be soldered or not, as desired.

Aluminum Tube Joint. — Aluminum conductors of sizes up to about one-half inch diameter are usually jointed by inserting the two ends side by side into a flat aluminum tube, which is then given 3 or 4 twists as shown in Fig. 11 by means of a special kind of tongs called connectors.

Pressed Aluminum Joint. — Aluminum conductors larger than one-half inch in diameter are more often jointed by dovetailing the strands, or by mechanical clamps such as the Dossert connector (*see below*), or by inserting the wires into a cast aluminum sleeve which is squeezed hydraulically until the conductors and sleeve flow into a solid homogeneous mass.

Dossert Joint and Connector. — The Dossert joint, shown in Fig. 12, consists of a compression sleeve which is slipped over the conductor, a screw on

Fig. 12.

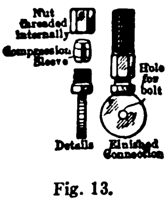

Fig. 13.

the lug proper and a nut threaded with a taper thread. The sleeve containing the conductor is thrust into the lug, with the nut over it. The nut is then tightened until the reaction of the tapered surface and the sleeve gives rise to a pressure of several thousand pounds per square inch, thereby making good electrical contact.

The Dossert connector or terminal is similar in construction, and is shown in Fig. 13.

COSTS. — The "base" price per pound of bare wire is usually about 1 cent more than the market price of ingot copper or "wire-bar." The following table (*from the American Steel & Wire Co.'s catalogue*) gives the extra charge in cents per pound for drawing, tinning and stranding.

CENTS PER POUND ABOVE BASE PRICE FOR DRAWING, TINNING AND STRANDING

Size A.W.G.	Drawing	Tinning	Stranding into cable or cord.
0000–8	—	¾	½
9	⅛	¾	¾
10	⅛	¾	¾
11	¼	¾	¾
12	¼	¾	¾
13	½	1	¾
14	½	1	1¼
15	¾	1	1¼
16	¾	1	1¼
17	1	1	2
18	1	1¼	2
19	1¼	1¼	2
20	1¼	1½	2
21	1⅝	1¾	5
22	1⅝	2	5
23	2½	2½	5
24	2½	3	5

Example. — If the market price of ingot copper were 16 cents per pound a cable composed of tinned No. 20 wires would cost 16 + 1 + 1¼ + 1½ + 2 = 21¾ cents per pound. For price of aluminum wire, see remarks in article on *Aluminum*.

WIRES AND CABLES, INSULATED. — (*See also Aluminum; Capacity and Charging Current; Copper; Distribution Lines; Electrolysis; Inductance and Inductive Reactance; Insulating Materials; Resistance; Skin Effect; Standardization Rules of the A.I.E.E.; Transmission Lines; Wires and Cables, Bare; Wires, Resistance.*)

The following is a brief table of contents of this article:

TERMINOLOGY. — The terminology employed in referring to wires and cables is at present in a very confused state, the same term being used with several different meanings. The following terminology is based upon a study of this subject by the Bureau of Standards, and upon a canvass of wire manufacturers and users made by the author of this article, and is quoted from the *Standardization Rules of the A.I.E.E.* (July 1914).

321.* **Wire.** — A slender rod or filament of drawn metal.

The definition restricts the term to what would ordinarily be understood by the term "solid wire." In the definition the word "slender" is used in the sense that the length is great in comparison with the diameter. If a wire is covered with insulation, it is properly called an insulated wire. While primarily the term "wire" refers to the metal, nevertheless when the context shows that the wire is insulated the term "wire" will be understood to include the insulation.

322. **Conductor.** — A wire, or combination of wires not insulated from one another, suitable for carrying a single electric current.

The term "conductor" is not to include a combination of conductors insulated from one another, which would be suitable for carrying several different electric currents.

Rolled conductors (such as bus-bars) are, of course, conductors, but are not considered under the terminology here given.

323. **Stranded Conductors.** — A conductor composed of a group of wires or any combination of groups of wires.

The wires in a stranded conductor are usually twisted or braided together.

324. **Cable.** — (1) A stranded conductor (single-conductor cable); or (2) a combination of conductors insulated from one another (multiple-conductor cable).

The component conductors of the second kind of cable may be either solid or stranded, and this kind of cable may or may not have a common insulating covering. The first kind of cable is a single conductor, while the second kind is a group of several conductors. The term "cable" is applied by some manufacturers to a solid wire heavily insulated and lead-covered; this usage arises from the manner of the insulation, but such a conductor is not included under this definition of "cable." The term "cable" is a general one and in practice it is usually applied only to the larger sizes. A small cable is called a "stranded wire" or a "cord," both of which are defined below. Cables may be bare or insulated, and the latter may be armored with lead or steel wires or bands.

* Numbers are the paragraph numbers of the Standardization Rules of the A.I.E.E. (q. v.).

325. **Strand.**—One of the wires or groups of wires of any stranded conductor.

The majority of American copper wire manufacturers have used the word "strand" to designate a group of bare wires twisted together.

326. **Stranded Wire.** — A group of small wires, used as a single wire.

A wire has been defined as a slender rod or filament of drawn metal. If such a filament is subdivided into several smaller filaments or strands and is used as a single wire, it is called a "stranded wire." There is no sharp dividing line of size between a "stranded wire" and a "cable." If used as a wire, for example, in winding inductance coils or magnets, it is called a stranded wire and not a cable. If it is substantially insulated, it is called a "cord," defined below.

327. **Cord.** — A small cable, very flexible and substantially insulated to withstand wear.

There is no sharp dividing line in respect to size between a "cord" and a "cable," and likewise no sharp dividing line in respect to the character of insulation between a "cord" and a "stranded wire."

328. **Concentric Strand.** — A strand composed of a central core surrounded by one or more layers of helically laid wires or groups of wires.

329. **Concentric-lay Cable.** — A single-conductor cable composed of a central core surrounded by one or more layers of helically laid wires.

330. **Rope-lay Cable.** — A single-conductor cable composed of a central core surrounded by one or more layers of helically laid groups of wires.

This kind of cable differs from the preceding in that the main strands are themselves stranded.

331. **N-Conductor Cable.** — A combination of N conductors insulated from one another.

It is not intended that the name as here given be actually used. One would instead speak of a "3-conductor cable" and a "12-conductor cable," etc. In referring to the general case, one may speak of a "multiple-conductor cable" (as in definition § 324 above).

332. **N-Conductor Concentric Cable.** — A cable composed of an insulated central conducting core with (N-1) tubular stranded conductors laid over it concentrically and separated by layers of insulation.

This kind of cable usually has only 2 or 3 conductors. Such cables are used in carrying alternating currents. The remarks on the expression "N-Conductor" given for the preceding definition apply here also.

333. **Duplex Cable.** — Two insulated single-conductor cables twisted together.

They may or may not have a common insulating covering.

334. **Twin Cable.** — Two insulated single-conductor cables laid parallel, having a common covering.

335. **Triplex Cable.** — Three insulated single-conductor cables twisted together.

They may or may not have a common insulating covering.

336. **Twisted Pair.** — Two small insulated conductors twisted together without a common covering.

The two conductors of a "twisted pair" are usually substantially insulated, so that the combination is a special case of a "cord."

337. **Twin Wire.** — Two small insulated conductors laid parallel, having a common covering.

CONSTRUCTION OF INSULATED WIRES AND CABLES.— Data on the manufacture and properties of insulating materials will be found in the articles on *Cambric, Varnished; Gutta-percha; Paper, Impregnated; Rubber; Insulating Materials, Miscellaneous.* Data on the conductor itself will be found in the articles on *Copper; Aluminum; Wires and Cables, Bare.*

Conductors. — Round copper wire, solid or stranded, is almost invariably used for insulated wires and cables. Aluminum, requiring a larger cross-section for the same conductance per unit length, requires more insulating material for the same thickness of insulation. Aluminum cables, however, are sometimes provided with a weatherproof covering.

Sector-shaped Conductors. — Multiple-conductor cables with sector-shaped conductors are in successful use in Europe, their advantage being that they may be assembled in less space than round conductors. P. Humann (*Elek. Zeit., 1910, vol. 31, p. 1265-1207*) says that tests and theory both demonstrate that the sharp corners give rise to excessive dielectric stresses at high voltages.

Preparation of Conductors for Insulation. — Particularly where rubber insulation is used it is necessary to cover the conductor with a thin film of tin or with a layer of soft cotton threads.

Tinning. — Low-grade and perhaps other rubber compounds react with copper to the detriment of both insulation and wire. It is, therefore, the invariable practice to tin copper under rubber, although it is not definitely known whether tinning is necessary with high-grade 30 per cent Para compounds. It is often stated that the copper is corroded by the *free* sulphur, but the author has known of cases where over ten times as much copper was consumed as could combine into Cu_2S, with the free sulphur actually present.

Separators. — Small stranded conductors are usually covered with a winding of soft cotton threads to prevent adhesion between the wire and insulation, and thereby facilitate the removal of insulation at joints. Larger conductors are sometimes provided with a dry muslin separator for the same purpose.

Insulation. — The materials used for insulation are vulcanized rubber, gutta-percha, varnished cloth, impregnated paper, asbestos, cotton and silk thread, enamel, etc.

Rubber Insulation. — There are three processes by which rubber compound is put on wire, the straight strip, the helical tape and the tube or seamless processes. By the first, the compound is first made into long narrow strips and then pressed around the wire; by the second, a rubber tape is wound spirally around the conductor; by the last, the wire is run through a die through which the compound is pressed on to the wire. Insulation made by the former process shows a seam or ridge where the sides of the strip have united, unless a tape is applied before vulcanization, while that made by the tube process is seamless.

It might be expected that the seam of strip-laid insulation would be electrically weak, but in practice this is found not to be the case with high-grade compound, the insulation practically never puncturing at the seam.

Gutta-Percha is applied to the wire in the same manner as rubber.

Varnished Cloth. — The prepared cloth is applied to the conductor in the form of tape wound on helically and reversed every two layers, with overlapping joints staggered in successive layers. A thin layer of a non-hardening viscous filler is applied between layers.

Impregnated Paper. — Strips of Manila paper are applied helically and then thoroughly impregnated with an insulating compound.

Asbestos is applied in the form of threads or tape, usually in several layers. One or more layers of varnished cloth are sometimes used to separate the groups of asbestos tapes, and the whole is covered with a protecting braid.

Cotton and Silk. — Cotton or silk insulation consists of one to three layers of threads spun on to the wire.

Enamel. — This type of insulation is suitable only for wires under 5 mils in diameter. Cellulose acetate is a common form of enamel. A solution of cellulose acetate is applied to revolving coating rolls, which, in turn, deposit it on the moving wire. The quantity of solution placed on the wire must be adjusted to a nicety. After receiving its coating of solution, the wire passes through an oven at the rate of several hundred feet per minute. The volatile solvent is here driven off and the coating hardened, after which the process is repeated until numerous coatings have been applied. This method insures an even distribution of the film over the whole surface of the wire (*R. Fleming*).

Fillers. — Dry jute is used as a filler between the insulated conductors of multiple-conductor cables, being placed directly in contact with the insulation. Tarred or asphalted jute is used as a filler between the sheath and armor of armored cables.

Protective Coverings. — Coverings of treated cotton, hemp, paper, reinforced rubber, and lead are used to protect cables from mechanical injury and arcing.

Cotton Braid. — The most common covering for rubber-insulated conductors is a cotton braid saturated with a weatherproof compound composed principally of mineral wax. For some purposes, flameproof paint is used instead of wax compound.

Hemp Braid. — Hemp is sometimes used instead of cotton for braids on large cables which are likely to be exposed to unusually rough treatment. Six-lea is the most usual size for this service. The hemp is saturated with mineral wax compound, in the same way as cotton braid.

Weatherproofing. — Treated cotton braid is also put on uninsulated hard-drawn copper wire for overhead service, in order to protect the wire from destructive arcing due to accidental contact with tree branches and other foreign bodies.

Fireproof Paper. — Johnson & Phillips of Charlton, England, make an impregnated paper covering, which, under the influence of a flame, gives off gases in which a flame cannot exist. Tests have shown that the cable may become red hot from an internal short-circuit without setting fire to the insulation. (*Elect. Age, July, 1907.*)

Reinforced Rubber. — A form of cable covering, combining both insulation and mechanical protection, is composed of alternate layers of rubber compound and rubber impregnated fabric, which are vulcanized together after assembling, the finished product being similar to air-brake hose. The electrical and mechanical properties may be varied by varying the thickness and quality of rubber compound and the number of layers of fabric. It is practically waterproof and very strong mechanically. (*Safety Insulated Wire & Cable Co.*)

Lead Sheath. — The only thoroughly waterproof cable covering yet devised is a lead sheath. It is put over the insulation by passing the cable through a die while hot lead is pressed hydraulically around it through an annular die, forming a continuous and close-fitting pipe. Were it not for electrolytic corrosion, it would be practically permanent. Unfortunately lead is very subject to electrolytic and even chemical corrosion. It is also rendered brittle and eventually breaks into pieces when exposed to vibration, this effect being due to crystallization. Pure lead is suitable for cables which are hard and compact. Other cables require a small quantity of tin to harden the lead. For a

given thickness pure lead is cheaper, but for a given tensile strength a 3 per cent tin alloy is cheaper.

Antimony has recently been used instead of lead, with very satisfactory results and a material saving in cost, especially with telephone cable.

Armor Wire and Tape. — Submarine cables and cables made to be buried direct in the ground are usually given a mechanical protection of galvanized-steel armor in the form of wires or tapes.

APPLICATIONS OF VARIOUS TYPES OF CABLES. — The type of insulation and protection to employ in any instance depends upon the purpose for which the conductor is to be used and the place in which it is to be installed.

Power Cables, that is, cables for the transmission of electric energy, may be installed in or on buildings, in cars, on pole lines under ground or under water.

Power Cables on Overhead Structures. — Insulated conductors supported on structures subject to vibration are usually made with rubber, varnished cloth or a combination of the two, with a steel armor or a heavy braiding. Insulated conductors in buildings and on cars are almost invariably made with rubber, covered with a saturated cotton braid.

Underground Cables are usually installed in ducts and are commonly made with paper or varnished cambric and a lead sheath. Where mechanical injury is to be guarded against, the sheath should be covered with asphalted jute and a steel band or wire armor.

Long-distance transmission by underground cables is seldom resorted to on account of the expense of conduit lines. There is no especial difficulty attending the manufacture of cables for three-phase voltages from 25,000 to 50,000 volts between conductors, the neutral being grounded. For such high potentials, it is generally necessary to grade the insulation so as to eliminate steep potential gradients.

According to L. Lichtenstein (*Elek. Zeit., 1910, Vol. 31, p. 773*) a reliable three-conductor cable for 50,000 volts is now available with a perforation e.m.f. above 330,000 volts. M. J. Grosselin (*La Revue Elec., 1910, Vol. 14, p. 92*) says that 2.6 kilometers and 4.5 kilometers of 3-phase 40,000-volt ungraded cable are in use by the Girod plant at Ugine and by the Grenoble Lighting & Power Co., respectively.

Submarine Cables are usually insulated with rubber, sheathed in lead and armored with wire or steel bands. With high-grade rubber compounds, the sheath may be omitted. Recently, however, paper-insulated lead-sheathed and armored submarines have come into use.

Insulated Conductors for Instrument and Machine Windings. — Enameled wire or wire insulated with cotton or silk is used for the former, while varnished cambric, mica and asbestos compounds are used for the latter.

Insulated Conductors for Telephony, Telegraphy and Signaling. — Underground telegraph and telephone cables are almost invariably insulated with dry paper and sheathed in lead, although rubber is used as insulation where a lead sheath is not permissible. Submarine telegraph cables are usually insulated with gutta-percha, protected with a lead sheath and armor. Rubber insulation of the highest grade is demanded for railroad signal purposes, the usual mechanical protection being cotton braid saturated with mineral wax compound.

THICKNESS OF INSULATION. — In the case of a single-conductor cable a simple formula can be deduced for the proper thickness of insulation to withstand a given electric stress. Such a formula, however, involves certain

assumptions which are only partially realized in practice. These assumptions are:

a. That the radial depth of the insulation or dielectric is the same at all points, i.e., that the cross-section of the cable is a perfect circle with the conductor section (also a perfect circle) exactly in the center of the insulation. Due, however, to the crinkling of tape, the pressure of the braid, or other accidents of manufacture, this is never the case. The eccentricity of the conductor with respect to the insulation may, however, be allowed for by adding to the theoretical thickness of insulation an additional thickness, known as the "error thickness" or excess thickness.

b. That the dielectric is perfectly homogeneous throughout. This is only partially realized in practice. It is probable that even in the most carefully made insulation there is a minute amount of moisture, but sufficient to modify considerably any conclusions based on absolute homogeneity of the dielectric.

c. That when the electric stress, or potential gradient (per inch, say) at any part of the dielectric exceeds a certain value F, known as the dielectric strength of the dielectric, that part of the dielectric becomes a conductor even though there is no actual rupture or puncturing. The nature of this partial breakdown is not understood, but there is considerable evidence to show that such an effect exists (*see discussion by Middleton, Trans. A.I.E.E., 1910, Vol. 29, p. 1587, and Del Mar, Trans. A.I.E.E., 1911, Vol. 30, p. 238*). As far as is known this partial breakdown is not permanent, but the insulation returns to its original state when the stress is removed.

Theoretical Thickness of Insulation. — Let

H = potential gradient, in volts per inch, at any point P in the dielectric at a distance x from the center of the wire, Fig 1,

V = volts between wire and sheath (or outside surface of insulation),

r = radius of wire, in inches,

R = outside radius of insulation, in inches,

F = dielectric strength of the insulation, in volts per inch.

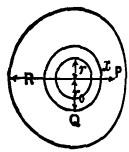

Fig. 1.

Then, on the assumption of a perfectly homogeneous dielectric and perfect symmetry between conductor and insulation,

$$H = \frac{V}{x \log_e \left(\frac{R}{r}\right)}.$$

That is, the potential gradient is the greatest at the surface of the conductor and decreases toward the outer surface of the insulation as shown in Fig. 2. The potential gradient at the surface of the conductor is

$$H_s = \frac{V}{r \log_e \left(\frac{R}{r}\right)}.$$

For the same outside diameter of the insulation this stress at the surface varies with the radius of the conductor as shown in Fig. 3, and has a ***minimum*** value when the radius of the conductor r equals the outside radius of the insulation R, divided by the base ϵ of the natural system of logarithms, that is, when $r = R/2.72$.

Consequently, if the breakdown of a cable is a progressive action, i.e., if the insulation breaks down close to the wire and then the breakdown spreads out through the insulation, it is evident, from Fig. 3, that if r is greater than $R/2.72$,

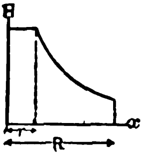

Fig. 2.

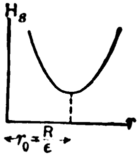

Fig. 3.

and the impressed voltage V is such as to produce a stress H_s at the surface of the conductor in excess of F, then as successive layers of the insulation break down, H_s at each new conducting surface thus formed will be greater than F, and the breakdown will rapidly extend to the sheath. If, however, r is less than $R/2.72$, then a value of H_s in excess of F will break down only a sufficient layer of insulation to render the value of H_s at the new conducting surface thus formed just equal to F.

Therefore, on the basis of the assumptions noted in the preceding section, the maximum voltage which a cable can withstand is equal to

$$V_m = Fr \log_\epsilon \left(\frac{R}{r}\right),$$

provided r is greater than $R/2.72$, but when r is less than $R/2.72$ the maximum voltage is

$$V_m = Fr_0 \log_\epsilon \left(\frac{R}{r_0}\right) = \frac{RF}{2.72},$$

and is *independent of the radius of the conductor.*

A more complete account of the theory of ungraded cables is in the *Trans. A.I.E.E., 1910, Vol. 29, p. 1614*, and a paper on graded cables by H. S. Osborne is in the *Trans. A.I.E.E., 1910, Vol. 29, p. 1553.*

Practical Determination of Insulation Thickness. — On account of the numerous assumptions which must be made in determining the necessary thickness of insulation from any simple theory, such as outlined above, a rule-of-thumb method, based on experience, is usually employed in practice.

The following tables represent current practice. With respect to rubber insulation the Underwriters' Rules give minimum thickness, and the Signal Engineers' specifications give maximum thickness. Similar tables are given by J. Langan (*Trans. A.I.E.E., 1906, Vol. 25, p. 200*) and W. A. Del Mar (*Electric Power Conductors, 1914*) the theoretical basis of the last-named tables being also given. See also report of Wire Committee of the Association of Railway Electrical Engineers, 1913.

RUBBER INSULATION

Thickness of Insulation in 64ths of an Inch

* Above working voltages are based on all conductors of the circuit being insulated. For d-c. 600-volt railway single-conductor, leaded cables, use 2,000-volt class. For three-phase "Y"-connected circuits with grounded neutral and three-conductor cables, thickness of insulation between conductors and ground need only be 7/10 of that between conductors. (*G. E. Bulletin No. 4787.*)

Cotton, Silk and Enamel.—The thicknesses rated by various manufacturers as "single," "double" and "triple" covered differ by several mils; see article on *Electromagnet Windings*. Enamel insulation will stand a working potential of about 500 volts alternating per mil of thickness. Silk or cotton will stand about one-quarter as much.

WEIGHT OF INSULATED WIRES AND CABLES.—So many variables enter into the weight of an insulated wire or cable, and there are so many forms in use, that it is impossible to give comprehensive tables here. The reader is referred to the catalogues and circulars of the manufacturing companies. When such sources of data are not available the weight may be calculated from the dimensions of the cable by finding the sum of the weights of the conductors and the weights of the insulation, braid, tape, sheath, etc. The weight of the conductor may be found in the wire tables under *Wires and Cables, Bare*. The weight of the insulation, braid, tape or sheath, may be found by calculating the cross-section of each of these materials and multiplying by the length of the cable and a factor proportional to the density of the material; see table accompanying.

The cross-section of a tube having an internal diameter d and thickness t is $\pi t(d + t)$. When the diameter and thickness are in inches and the specific

gravity of the material forming the tube is δ, then the weight in pounds per 1000 ft. of tube is

$$W = 1362\,\delta t\,(d + t).$$

The values of the specific gravity δ, the product $1362\,\delta$, and the weight per cu. in., for the various materials used in the construction of cables are given in the accompanying table. From this relation the weight per 1000 ft. of any tubular (circular cross-section) layer of insulation, braid, tape or sheath may be readily calculated. The formula is, therefore, directly applicable to single-conductor cables.

The weight of duplex or triplex cables is calculated as for a group of single-conductor cables, except with regard to the fillers. The cross-section of the filling material is most readily calculated by subtracting from the cross-section of the entire cable the cross-sections of the individual conductors and the tubular insulation, sheath, etc. The weight of twin cables can also be readily found by calculating the cross-section of the various parts in inches and multiplying by the length and the proper density factor.

The weight of separators in lb. per 1000 ft. is usually between 5 and 10 times the mean diameter, expressed in inches, of the conductor and separator.

WEIGHTS OF CABLE INSULATION

Material	Specific gravity	Pounds per cubic inch	$1362\,\delta$
	δ	$0.03613\,\delta$

INSULATION RESISTANCE. — The insulation resistance of a cable is usually expressed in megohm-miles, sometimes erroneously called megohms per mile. The total insulation resistance of a cable varies inversely as its length, e.g., a cable two miles long has half the resistance between conductor and sheath of a length of one mile of this cable. The formulas for insulation resistance of various types of cables are given below.

Single-conductor Cable. — In absolute units the insulation resistance of a length of l centimeters of such a cable is

$$R' = \frac{\rho}{2\pi l}\log_e\frac{D}{d},$$

where d = diameter of conductor, D = outside diameter of insulation, R = insulation resistance, l = axial length, ρ = specific resistance. From the above formula the megohm-miles are

$$R = k \log_{10} \frac{D}{d},$$

where $k = 5.8 \times$ (specific resistance in millions of megohms per inch cube) and the two diameters are expressed either in inches or in centimeters. The value of k for various types of insulation at 60° F., after an electrification of approximately one minute under a constant d-c. voltage, is given in the accompanying table. k varies both with the time of electrification and with the temperature and is, as a rule, several thousand times greater for alternating currents than for direct currents (*see Insulating Materials, Miscellaneous*).

Insulation	k at 60° F.	
	Limits	Usual values
Vulcanized rubber.....	780 to 23,000	3000 to 8000
Gutta-percha..........		2500
Varnished cloth.......	500 to 4,000	700 to 1200
Impregnated paper.....	1000 to 3,000	1500

The tables on the following pages give the value of $\log_{10} \frac{D}{d}$ for various sizes of wire and thicknesses of insulation.

Two- and Three-conductor Cable in Lead Sheath. — The insulation resistance between the two conductors of a two-conductor cable is practically double that between each conductor separately and the sheath.

The insulation resistance of a three-conductor cable between any one conductor and the other two conductors and the sheath is approximately one-half of that between each conductor separately and the sheath. Simple formulas for these resistances in terms of the dimensions of the cable are not available, for the various parts of the coverings (insulation, fillers and braids) have different resistivities.

CAPACITY AND CHARGING CURRENT. — See article on *Capacity and Charging Current.*

INDUCTANCE, REACTANCE AND IMPEDANCE. — The formulas for bare wires and cables (*see Inductance and Inductive Reactance*) are also applicable to lead-sheathed insulated cables, the insulation and sheath producing practically no effect on the self inductance.

Resistance and Impedance of Three-conductor Cables. — The following table, published by the G. E. Co., is based upon 100 per cent conductivity copper at 75° F., with an allowance of 3 per cent for spiral path of the component wires, 60 cycles per second, and standard thicknesses of varnished cambric insulation.

RESISTANCE AND IMPEDANCE OF THREE-CONDUCTOR COPPER CABLES

The reactance is $x = \sqrt{z^2 - r^2}$; the inductance is $L = x \div 2\pi f$ where f is the frequency in cycles per second.

Resistance and Reactance of a Pair of Armored Single-conductor Cables. — Dr. J. B. Whitehead (*Trans. A.I.E.E., 1909, Vol. 28, p. 737*), gives the following formula for the self inductance of each of two parallel armored single-conductor cables:

$$L = 0.161 \left\{ 2 \log_e \frac{D}{r} + \frac{1}{2} \right\} + 0.078\,(k - 1),$$

where L = millihenrys per mile of each conductor,

D = distance between centers of conductors, any unit,

r = radius of each conductor, in same unit as D,

k = 14 to 36, depending upon the permeability of the armor wires.

The above-cited paper concludes as follows: 1. Theoretically the reactance of the usual type of single-conductor, iron-armored power cable may be from 2 to 4 times that of unarmored cable, depending on the distance to return conductor; the factor increases with decreasing distance. 2. In cables as manufactured, the reactance is about 0.7 of the maximum theoretical value as calculated by the above formula. 3. The effective resistance at 25 and 60 cycles is about 1.6 and 2 times respectively the d-c. resistance for a current density of 1 ampere per 1000 circular mils, and varies little with the distance between conductors. 4. The impedance for distances under 12 inches is about 3 times the d-c. resistance at 60 cycles and 1.7 to 2 times the d-c. resistance at 25 cycles. With the sheathing and the armor grounded at both ends the impedance is somewhat lessened and is largely of the nature of resistance. 5. The impedance of a double-conductor iron-armored cable with conductors located 0.875 inch apart between centers and at the current density given above is about 5 per cent greater at 60 cycles and 3 per cent greater at 25 cycles than the calculated value. The increase is in effective resistance, due to eddy currents in the lead sheathing.

H. W. Fisher (*Trans. A.I.E.E., 1909, Vol. 28, p. 747*) says that the impedance of armored cables cannot be calculated with any degree of certainty owing to the effect of slight differences in the air gaps between armor wires. He shows that a single-conductor No. 0 B. & S. cable armored with two flat bands of steel (0.39 × 1.5) may have a maximum effective resistance 8 times the d-c. resistance when the lead and armor are disconnected, and that under practical conditions of operation the ratio is about 3.5. With larger cables the ratio will be greater.

Unless the armor and lead of single-conductor cables are bonded together, arcs may occur between them and under water they would be injured by alternating-current electrolysis.

CURRENT-CARRYING CAPACITY OF WIRES AND CABLES. — The permissible temperature rise of insulated conductors usually depends upon the effect of heat on the insulation. In the case of rubber there is no well-defined temperature at which deterioration becomes especially rapid. The usual order of events when rubber is heated is as follows: Oxidation is accelerated if air is present; "devulcanization" commences, i.e., the rubber molecule breaks up without, however, liberating any sulphur; vulcanization proceeds, until all the free sulphur has combined with the rubber or mineral matter. The maximum working temperature is given as 130° F. (54.4° C.) by Melsom & Booth and 122° F. (50° C.) by the G. E. Co.

In the case of varnished cambric a temporary weakening occurs at a much lower temperature than any permanent deterioration, the insulation resistance falling quite rapidly and the dielectric strength decreasing, owing probably to the ionization of the separating oils. The same applies to paper in a somewhat less degree. These cables may therefore be worked at higher temperatures at low voltages than at high voltages, especially in the case of yellow varnished cambric which does not contain gilsonite or petroleum products. Paper is desiccated and impregnated at between 220° and 230° F. and no deterioration of the materials is observable even if the processes are considerably prolonged but the material does not insulate effectively for low-tension work above about 167° F. (75° C.)

Approximate Formula for Permissible Current. —

Let A = cross-sectional area of conductor, circular mils,
r = resistance per mil-inch of conductor at final temperature,
I = current in conductor, amperes,
C = circumference of conductor, inches,
w = watts dissipated per square inch of conductor surface, per degree Centigrade temperature rise. This will depend upon the thermal resistivity of the insulation and upon the nature of the radiating surface,
T = temperature rise, degrees C.

When the watts dissipated become equal to the watts generated, the temperature of the conductor will no longer rise and the current will have the value

$$I = \sqrt{\frac{ACwT}{r}}.$$

The above formula does not hold very accurately in practice on account of the approximations in the equation for watts dissipated. It is, however, useful for estimating the influence of various factors upon the carrying capacity.

Table of Current-carrying Capacity. — The following table gives the safe current per conductor as recommended by the authorities cited.

CURRENT-CARRYING CAPACITY OF COPPER CABLES

Amperes per Conductor

(For Aluminum Cables multiply the currents given in Table by 0.84)

Notes on above Table. — The columns headed National Electric Code give the requirements of the National Board of Fire Underwriters for interior wiring in buildings.

The columns headed General Electric Company are made up from a table published by this company in their bulletin No. 4787. The following notes are appended to this table in the bulletin.

"Concentric cables (one conductor inside the other, the latter forming a tube) will safely carry about 20 per cent less current in each conductor than the same size of single-conductor cable. Four-conductor cables, 10 per cent less than same size triple conductor. All temperatures refer to temperatures of copper core."

The values of the current given for three-conductor cables are approximately 78 per cent of the values given for single-conductor rubber-insulated cables for a rise of temperature of 30° C. above surrounding air at 20° C. This same factor may be applied to the values given for single-conductor cables in ducts in order to obtain the current-carrying capacity of three-conductor cables in ducts. The current-carrying capacity *per conductor* of twin-conductor cables is approximately the same as for single-conductor cables, while the current-carrying capacity *per conductor* of duplex cables (round) is about 15 per cent less.

The column headed Standard Underground Cable Co. is taken from the handbook issued by that company and applies to each of four equally loaded cables installed in adjacent ducts in the usual type of conduit system.

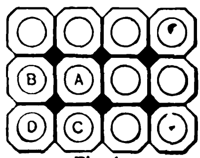

Fig. 4.

Cables in Ducts. — The following is also taken from the Standard Underground Cable Co's. handbook:

"Assuming that not more than twelve cables, arranged as shown in Fig. 4, can be used, the average carrying capacity may be taken as the criterion for the proper size of conductor; and for cables of a given type and size the carrying capacities of all cables, even though placed in adjacent ducts, will be represented by the following figures, taking unity as the average carrying capacity of four cables:

Number of Cables........	2	4	6	8	10	12
Multiplier...............	1.16	1.00	0.88	0.79	0.71	0.63

"**Rubber versus Paper.**— Rubber insulation is a somewhat better heat conductor than dry or saturated paper, and therefore, when applied to the same size conductor in equal thickness, will permit of a larger current flowing in the conductor for the same rise of temperature above the surrounding air. On the other hand, rubber deteriorates much more rapidly at high temperatures than saturated paper, and, while this disadvantage is apparently compensated for up to about 150° F. by its superior heat-dissipating qualities, at higher temperatures deterioration takes place and becomes so serious that its value as an insulating medium disappears in a comparatively short time.

"**Insulation Thickness.** — As the thickness of insulation is increased, the temperature of the conductor, with any given current flowing, gradually increases and therefore the current-carrying capacity becomes reduced. The reduction in capacity, however, is not very great, being in the ratio of about 93 for 14/32 insulation to 100 for 7/32 insulation, so that the values in the table given above should be slightly decreased when greater thicknesses than 7/32 are used.

"**Initial Temperature.** — As it is the final temperature reached which really affects the carrying capacity, the initial temperature of surrounding medium must be taken into account. If, for instance, the conduit system parallels steam or hot-water mains, the temperature of 150° F. (which is assumed in the above table to be the maximum for safe continuous work on cables) will be reached

with lower values of current than would otherwise be the case; and as 70° F. is the actual temperature we have assumed to exist in the surrounding medium prior to loading the cables, any increase over 70° F. must be compensated for by reducing the current carried.

"For rough calculations it will be safe to use the following multipliers to reduce the current-carrying capacity given in the table to the proper value for the corresponding initial temperatures:

Initial temperature, °F. . .	70	80	90	100	110	120	130	140	150
Multipliers.	1.00	0.93	0.86	0.78	0.70	0.60	0.48	0.34	0.00."

German Practice. — Tables giving the rules of the Verband Deutcher Elekiloteclniker for underground cables will be found in the *Elek. Zeit., 1907, Vol. 28, p. 500,* and the practice of the Siemens-Schuckert Werke for cables buried in the ground in the *Elek. Zeit., 1909, Vol. 30, p. 389.*

Cables Buried Underground, Under Water, etc. — A cable buried in earth will carry from 10 to 25 per cent more current with a given rise in temperature than it will when run in a dry duct, depending upon the character of the soil; immersed in water it will carry about 50 per cent more (*G. E. Bulletin, 4591*).

Current-carrying Capacity of Lead Sheath. — The carrying capacity of a lead sheath is given approximately by the following formula:

$$C = 128\sqrt{dp\,(d-p)T},$$

where

d = outside diameter of sheath in inches,
p = thickness of sheath in inches,
T = temperature rise, ° C.

Rise of Temperature with Time. — Fig. 5 shows the rise of temperature with time for a single conductor, 0.5 square inch in cross-section, carrying 750 amperes. Curves I to VI are from a paper by C. Beaver (*Jour. I.E.E., 1911*) and curve VII from Del Mar's *Electric Power Conductors.*

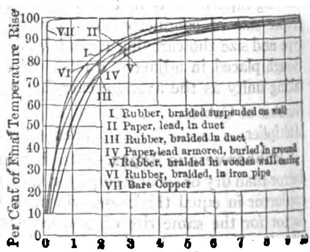

Fig. 5.

TESTS AND INSPECTION OF INSULATED WIRES AND CABLES.

— (*See also section on Specifications, below.*) Wires and cables are submitted to factory tests to ascertain whether they meet specified requirements. For the tests on the conductors themselves, see the article on *Wires and Cables, Bare.* The usual factory tests of insulation are the high-potential test and the measurement of insulation resistance and capacity. In the case of rubber insulation, the tensile strength and elasticity of the insulation are also measured. Insulated wires and cables are also tested after installation to discover incipient faults and to locate existing faults.

The tests described below in greatest detail are those employed by the majority of American cable manufacturers and operating engineers. Methods of measuring insulation resistance are described in the article on *Resistance and Conductance,* and methods of measuring capacity and inductance in the articles on *Capacity* and *Inductance.*

High-potential Tests. — The voltage which will break down the insulation of a given cable decreases as the length of the conductor is increased. For

this reason the potential tests of the National Board of Fire Underwriters, which are made upon one-foot lengths, are much too severe for commercial lengths. The chance of weak spots also increases with the conductor diameter making large cables dielectrically weaker than would be expected from theory based upon the assumption of homogeneous dielectrics. Large cables in long pieces are also likely to be overstressed momentarily upon the application of the voltage on account of the transient voltages caused by their electrostatic capacity. Furthermore, the manufacturers are unwilling to test large cables as near the limiting voltage as small cables on account of the greater commercial risk.

The breakdown voltage also decreases with the time of application. For example, a paper-insulated cable which breaks down at 2000 volts applied for 5 minutes will break down at about 1600 volts applied continuously for 30 minutes and at 1300 volts applied continuously for 60 minutes. On this account, the time of application of the test voltage as well as the value of this voltage should always be specified.

For the methods of measuring the voltage, see articles on *Insulating Material, Testing of; Spark Gap for Measuring High Voltage.*

Standard High-potential Tests. — In the following tables are given the test voltages recommended by the authorities noted for given thicknesses of various kinds of insulation.

All sizes	36	60.0	48	38.4	48	38.4	30.7
All sizes	36	62.5	50	40.0	50	40.0	31.9

Tests on three-conductor cables for circuits with grounded neutral, in proportion to thickness of insulation: Example, three-phase, 12,000-volt circuit "Y," neutral grounded, insulation on each conductor 3/16 inch (total between conductors 3/8 inch), outer belt 3/32 inch (total 9/32 inch); test pressure at factory for 5 minutes, between conductors 30,000 volts, each conductor to earth 22,500 volts. For mechanical reasons, thickness of insulation on individual conductors of three-conductor cables 3000 volts and less is made somewhat greater than required by working pressure on some sizes.

(The above tests are very conservative, some manufacturers advocating far severer tests.)

POTENTIAL TESTS FOR PAPER INSULATION

Potentials in Kilovolts

(G. E. Co. Bulletin 4787)

Size wire, A. W. G. or B. & S. and Cir. Mils	Thickness of insulation, 64ths in.	At factory			After installation

Tests on three-phase cables for grounded neutral in proportion to thickness of insulation: Example, three-phase 13,000-volt circuit "Y," neutral grounded, insulation on each conductor 5/16 inch (total between conductors 5/8 inch), outer belt 5/32 inch (total 15/32 inch); test pressure at factory for 5 minutes, between conductors 32,500 volts, each conductor to earth 17,500 volts.

High-potential Test at Factory. — The entire reel of cable, unless lead covered, should be set, with its ends projecting, in a tank of water. The braid, tapes, etc., should be removed from the insulation for a length depending upon the potential to be applied and the surface of the insulation thoroughly dried or dipped in hot paraffine. One terminal of a source of alternating e.m.f. is then connected to the conductor and the other to the water. In the case of lead-covered cables the second terminal is connected directly to the lead. In the case of multiplex cables, the potential is sometimes applied between conductors.

The source of e.m.f. is invariably a transformer, but various means are adopted for obtaining variations of potential. Among these means are:

1. Supplying the transformer from a special alternator whose voltage is varied by means of a field rheostat.

2. Making the primary and secondary windings movable in relation to one another, so as to vary the linkage of magnetic lines.

3. Applying the current to suitable taps in the low-tension windings of the transformer by means of a multi-point switch.

Tests for Faults in Sheath. — There are sometimes faults in the lead of lead-encased cables. In order to detect them the usual practice has been to place the cable for twenty-four hours in water and then measure its insulation resistance. V. Planer (*Elek. Zeit., Jan. 4, 1912*) has investigated whether this method is a really reliable test with modern cables. In several lead-encased cables insulated with impregnated paper, a number of holes were artificially made in the lead armor and the cables placed in water. Every twelve hours the insulation resistance of the cable was measured and the cable was tested every hour at double normal voltage. After the cables had been in water for twenty-four hours or forty-eight hours the insulation resistance was just the same as before. The measurements were repeated daily and the results remained unchanged after five weeks. A second cable was placed in the water without a lead covering so that the impregnated paper was directly in contact with the water. After four weeks the cables could still withstand the test with double the normal voltage, while the insulation resistance had decreased by 10 per cent. These experiments prove that to place a modern cable for twenty-four hours in water before testing it is not a reliable method for detecting a fault in the lead armor. The best way to test the lead armor is with water under pressure. Some German cable manufacturers use pressures of several atmospheres.

Mechanical Tests of Rubber. — The test piece should be carefully prepared avoiding incisions and irregularities. The best way to obtain a test piece from a small conductor is to wet a sharp knife and run it tangentially along the wire so as to cut off a strip of rubber of segmental cross-section. In the case of large conductors, the best plan is probably to remove the insulation, spread it out flat and cut off a piece of uniform width by means of a special cutter consisting of a pair of parallel knife blades attached to a common frame. The diagonal projections of rubber which occur on the inside of insulation stripped from stranded conductors are neglected in computing the cross-sectional area.

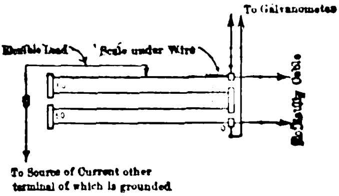
In order to measure its tensile strength the sample of rubber is held in some sort of grip and stretched in a machine similar to that used for wire (*see Bureau of Standards Bulletin No. 37*). It is usual to reduce the results thus obtained to pounds per square inch.

Seals. — Large purchasers of wire and cable assure themselves that they receive the material which they have inspected by sealing it at the time of inspection. Two sealing stamps are usually necessary, one for wire from No. 14 to No. 10 A.W.G. and one for wire from No. 8 to No. 4 A.W.G. These stamps press the purchaser's mark into the copper, Wires smaller than No. 14 A.W.G. are too small to show such a mark and are therefore sealed by looping a loose end into a lead seal and pressing this tight with a stamp which leaves the purchaser's mark upon the lead.

Tests after Installation. — A high-potential test with the voltages given above in the tables is usually applied to the full length of cable immediately after installation and at regular intervals to detect incipient faults. Double line voltage is frequently used for the periodic tests. Grounds or crosses of relatively low resistance may be detected by bridge methods or by exploration, as described below.

Some engineers make periodic insulation-resistance tests and plot the results as a curve. If the curve manifests any decided downward tendencies the cause **is immediately** sought for. The methods of making these tests are given below.

Testing for Faults by Murray Bridge Methods. — The bridge used in the Murray loop tests is shown diagrammatically in Fig. 6. It consists essentially of a resistance wire graduated into two equal scales each reading from 0 to 100, the zero points being at the ends of the wire. A galvanometer is connected across the zero points and a flexible lead connected to the positive terminal of a source of direct current is put in sliding contact with the wire. The negative terminal of the direct-current source is grounded.



Arrangement of Bridge
Fig. 6.

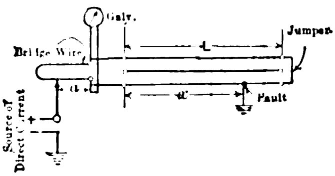


Fig. 7.

One Conductor Grounded. — When one conductor of a multiple-conductor cable is grounded, the bridge is connected as shown in Fig. 7, a jumper being placed between the faulty conductor and one of the others. The sliding contact is moved along the bridge wire until the galvanometer deflection becomes zero. Let a = distance of sliding contact, on bridge scale, to the terminal of the bridge connected to faulty wire, as a percentage of the length of the bridge wire, and L = length of cable; then if x is the distance from the bridge to the fault,

$$x = \frac{aL}{100}.$$

Two Conductors Crossed. — When one conductor of a three-conductor cable is crossed with another, the bridge is connected as shown in Fig. 8, a jumper

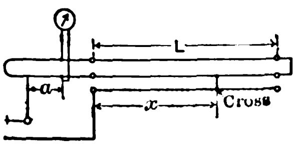

Fig. 8.

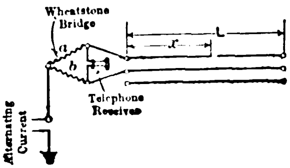

Fig. 9.

being again used, although connected differently. Zero reading is obtained on the galvanometer as before, and, using the same notation,

$$x = \frac{aL}{100}.$$

One Conductor Open. — When one conductor is open, the bridge is connected as shown in Fig. 9, a telephone receiver being substituted for the galvanometer, and alternating current for the direct current. The sliding contact is moved along the bridge until silence is obtained in the telephone.

Let a = distance from sliding contact to the terminal of bridge connected to open conductor,

b = distance from sliding contact to the terminal of bridge connected to whole conductor: then,

$$x = \frac{b}{a} L.$$

Ayrton's Method to Detect Crosses. — In Fig. 10, a, b and r represent three arms of a Wheatstone bridge, the fourth arm being the conductor N, which is in contact with a second conductor M of the same cable at the point P. Ground the conductor N at the far end and let x and y be the resistances

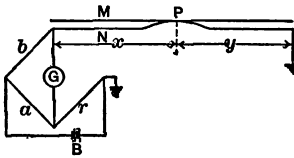

Fig. 10.

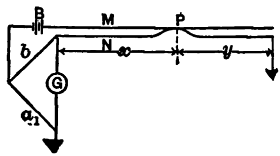

Fig. 11.

of the grounded conductor from the bridge to P and from P to the grounded end respectively. Let a, b and r be the resistances of the other three arms of the bridge. Make $a = b$, and adjust the variable resistance r until the galvanometer shows no deflection; then

$$x + y = r,$$

neglecting the resistance of the ground.

Then connect battery to M instead of to earth as shown in Fig. 11, and adjust a to a value a_1 such that the galvanometer shows no deflection. Then $a_1 x = by$ or

$$\frac{x}{x+y} = \frac{b}{b+a_1}.$$

But from first arrangement $x + y = r$, whence

$$x = \frac{br}{b+a_1}.$$

From the resistance of the conductor per foot, the distance to the point P is then immediately determined.

Varley Loop Test for Grounds. — Grounds may be located by the arrangement shown in Fig. 12. Loop the bad wire at the distant end with a good one of equal resistance. Call the resistance of the good wire c and the resistance to the fault on the bad wire x. Adjust the rheostat until the galvanometer balances. Then

$$x = \frac{2\,bc - ar}{a+b},$$

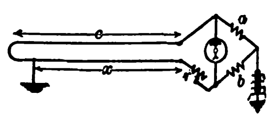

Fig. 12.

a, b and r being the values of the bridge arms and rheostat respectively when the galvanometer shows no deflection. (*S. G. McMeen.*)

Varley Loop Test for Crosses. — This is made by substituting one of the crossed wires for the earth path of Fig. 12, using one good wire as before.

Cable Tests by Exploring Coil. — Grounds on wires in cables can be located by the use of a telephone receiver connected to an exploring coil. To do this, connect a source of interrupted current to one end of the wire in trouble, the other terminal of the source being grounded. Remove from the wire in trouble all the grounds other than the fault. Then move along the cable a coil such as one spool of an 80-ohm telephone ringer (*see Telephony*), across whose terminals a receiver is connected. Hold the exploring coil with its iron core at right angles to the cable. A tone from the interrupter should be heard when the exploring coil is between the fault and the source of sound, but not when it is beyond the fault. (*S. G. McMeen.*)

Listening Tests on Telephone Lines. — A long telephone line will be noisy if one of its wires is grounded, open or crossed with a third wire, whether the latter be grounded or clear. To determine where the fault is, listen on the line while assistants short-circuit it at different places. The fault is beyond the short-circuit if the short-circuit makes the line quiet (*S. G. McMeen.*)

Use of Various Methods of Testing for Faults. — Two electric lighting companies (*N. E. L. A., 1911*) gave the following data on testing for faults: the relative number of tests for faults made by the different methods, and the cost per test of each type.

	Company A	Company B	Cost to Company B
	Per cent	Per cent	
Loop test	15.0	46	$12.00
Examination	36.5	8	12.00
Cut and try	17.5	28	60.00
Reported	24.3	11	2.50
Exploring coil	1.3	7	20.00
Miscellaneous	5.4	..	.....
	100.0	100	

SPECIFICATIONS. — (*See also article on Wires and Cables, Bare.*) The following forms are recommended for insulated wire and cable specifications. The general idea is for the purchaser to have printed or mimeographed forms and to fill them in according to specific requirements. These tabular specifications are supplemented by general specifications for workmanship and materials, which should be included when bids are sought or orders given. This arrangement minimizes the chance of accidental omission on the part of the purchaser and manufacturer and saves the bidder time in reading long specifications.

Items to be Covered in Detail Specification. —
Specification No.,
Title,
State briefly the service for which the conductor is intended,
Number of separately insulated conductors,
Material of conductors,
Type of stranding (parallel, concentric or rope),
Number of strands per conductor,
Number of wires per strand (if rope strand),
Total area of conductor or A.W.G. No.,
Conductor shall *not* be tinned (omit the word "not" as required),
Type of separator, if any,

Insulation material, each conductor,
belt,
Minimum thickness of insulation, each conductor,
belt,
Tape, material,
Number of tapes, each conductor,
over each layer,
over-all,
Pressure wire (if any), size,
insulation,
location,
Servings, material,
number,
thickness, inches,
Braid, material,
number on each conductor,
number over-all,
Tracers (if required), material,
number,
arrangement,
Laterals (if required), material,
Filling under sheath,
Sheath material,
Thickness of sheath,
Filling between sheath and armor, material,
thickness, measured after armoring,
Armor, material, wire or band,
Jute over armor,
Maximum over-all diameter (if limit is necessary),
Length, maximum,
minimum,
Whether to be supplied in coils or on reels,

All workmanship and materials shall conform with the General Wire and Cable Specifications given in next paragraph.

GENERAL WIRE AND CABLE SPECIFICATIONS. — The following general specifications are to be used in conjunction with the above. These are offered merely as suggestions, as every engineer should be guided by personal experience and local requirements. The specifications of the Association of Railway Electrical Engineers have been largely drawn upon in preparing them.

Tests and Inspection. — The wire or cable shall be open for inspection by an authorized representative of the Purchaser, who shall be afforded all the necessary facilities for making the specified electrical tests and to assure him that the materials used and the process of manufacture conform with the specifications.

The Contractor shall notify the designated representative of the Purchaser sufficiently in advance of the completion of the wire or cable to enable inspection to be arranged for.

Measurement of Cross-section. — The combined area of the wires when laid out straight and measured at right angles to their axes shall be not less than the specified gage or circular mils.

Thickness of Insulation. — Unless otherwise specified, wires and cables shall be insulated in accordance with the National Electric Code requirements as given above in the section on *Thickness of Insulation.*

Stranding. — Unless otherwise specified, cables shall be stranded in accordance with the accompanying table (which is that proposed by the Bureau of Standards).

Size wire, A.W.G. or B. & S. and Cir. Mils	Number of component wires per conductor
2,000,000–1,600,000	127
1,500,000–1,100,000	91
1,000,000–550,000	61
500,000–250,000	37
0000–1	19
2–8	7

Tinning. — The wire shall be provided with a heavy uniform coating of tin without projections.

Samples of wire, before stranding or covering, shall be thoroughly cleaned with alcohol and immersed in hydrochloric acid of specific gravity 1.088 and temperature 60° F. for one minute. They shall then be rinsed in clear water and immersed in a solution of sodium sulphide of specific gravity 1.142 for thirty seconds and again washed. This operation shall be repeated three times and upon the completion of the fourth cycle, the sample shall show no sign of blackening.

The sodium sulphide solution must contain an excess of sulphur and should have sufficient strength to thoroughly blacken a piece of clean untinned copper wire in five seconds.

Separator. — The separator may consist of soft cotton yarn (which may be braided), or of paper or muslin tape. With untinned conductors, the separator shall completely cover the conductors; with tinned conductors, it is desirable that the separator shall allow the insulation sufficient contact with the conductor to prevent the conductor sliding in the insulation.

Rubber Insulation. — *(See also article on Rubber.)* Various grades of rubber insulation may be used with advantage, according to the degree of permanence desired. Rubber compounds, being composed of a mixture of organic and inorganic substances and their compounds, are too complex to permit of their permanency being predicted from theoretical considerations based upon tests of chemical and physical properties. It is therefore necessary to rely entirely upon experience and to write specifications which will require all new material to be substantially identical with insulation which has been found satisfactory in service.

At the date of going to press, the subject of standard rubber specifications is receiving a great deal of attention from committees of technical societies and by committees appointed by the large consumers and manufacturers. The general tendency is to specify a combination of chemical, mechanical and electrical requirements. The idea of the chemical clauses is that by specifying close limits upon the following analytical results (obtained by a standard method of analysis), the use of non-permanent substances will be substantially prevented.

Analytical results upon which limits are placed	Deleterious substances whose use is prevented by limits upon analytical results
Total sulphur.	Reclaimed rubber.
Alcoholic potash extract.	Rubber substitutes.
Chloroform extract.	Tars.
Mineral matter.	Carbon, cellulose, etc.
Saponifiable acetone extract.	Unextracted high resin rubbers.
Unsaponifiable acetone extract.	Deresinated rubber.

The mechanical clauses ensure sufficient vulcanization and assist in limiting the grade of rubber. The electrical clauses are to ensure the proper insulating qualities.

Where a high-grade rubber compound is to be purchased on the basis of competitive bids, the chemical clauses recommended by the "Joint Rubber Insulation Committee" (*Proc. A.I.E.E.*, Jan. 1914 and *Jour. Ind. & Eng. Chem.*, Jan. 1914) may be used in combination with the following mechanical and electrical clauses.

Concentric Application. — The compound shall be applied concentrically about the conductor and shall fit closely thereto. If necessary, in order to achieve this result on conductors of greater diameter than three-quarters of an inch, a tape shall be applied over the insulation before vulcanization. Such tape will be additional to any which may be required in the accompanying wire specification.

Repairs and Joints. — If exigencies of manufacture require repairs of joints in the insulation, the compound employed shall meet the mechanical and electrical requirements of this specification, and the work shall be done in such a way as to leave the repaired part or joint and all parts affected by it as strong and durable electrically as the remainder of the insulation. The repairs or joints shall be properly vulcanized in a mold of approximately the same diameter as the rest of the insulation.

Elasticity. — A sample of the insulation shall be stripped from the conductor, and cut to such a width as to give a cross-sectional area as near as practicable to one thirty-second square inch. The covering having been removed, marks shall be placed two inches apart on the sample, which shall then be stretched at the rate of twelve inches per minute until the marks are six inches apart and one end immediately released; thirty seconds after release the marks shall be not further apart than is specified in the following table.

Tensile Strength. — A strip of segmental cross-section shall be cut from the cable by means of a sharp knife held tangential to the conductor. The sample shall be bent in every direction to magnify and reveal any surface incision or imperfection which may exist. A portion of the sample without such defects and having a free length of not less than two inches shall then be stretched at the rate specified above until it breaks. Five samples from every 25,000 feet or less, shall be tested in this way and their average tensile strength shall be not less than one thousand pounds per square inch, or their minimum tensile strength less than nine hundred pounds per square inch. At the moment of fracture the average distance between marks shall be not less than specified in the following table:

Insulation thickness	Length after stretching and release, in.	Length at moment of fracture, in.
Less than 8/64 in.	2 7/16	9
8/64 in. to 12/64 in.	2 7/16	8
12/64 in. or over	2½	7

Electrical Tests. — Electrical tests shall be made upon all wire or cable after at least twelve (or 24) hours immersion in water while still immersed and before the application of any covering other than the tape or braid used in vulcanization. The insulated conductor shall successfully meet the specified

high-potential tests. The insulation resistance shall then be measured. In the case of rubber-insulated multiplex cables, the insulation resistance shall be measured before assembling the conductors. An additional electrical test shall be made on lead-covered cable only and shall consist of a high-potential test to be made upon the cable after assembling and leading and without immersion in water. In the case of multiplex cables this test shall be made successively between each conductor and the other conductors and sheath.

The insulation resistance shall be not less than specified (*see section above on Insulation Resistance*).

The temperature coefficient for correcting the insulation resistance to the standard temperature of sixty (60) degrees Fahrenheit shall be in accordance with the value given in the article on *Insulating Materials, Miscellaneous.*

Varnished-cloth Insulation. — (*Assoc. Ry. Elect. Eng., 1912.*) The insulation shall consist of a closely woven cotton cloth and a viscous filler. Each surface of the cloth shall have smooth continuous films of varnish and shall be free from wrinkles, blisters and all other imperfections. It shall be thoroughly impregnated with insulating compound, shall be pliable and shall have no tendency to crack when doubled on itself.

Filler. — The filler shall be a viscous moisture repelling insulating compound whose dielectric constant is similar to that of the varnished-cloth insulation and of such a nature that it will prevent the tapes from unwrapping when cut, but will allow the layers to slide upon each other when the cable is bent.

Assembly. — The insulating cloth shall be applied in the form of tape wound on helically and reversed at least every two layers. The tapes shall be of such widths that for different diameters of cable they will lie smoothly and be free from wrinkles; the turns shall overlap and the joints in successive layers shall be staggered. The filler shall be so applied between layers as to exclude all air, the whole forming a hard homogeneous semi-flexible wall of insulation.

Tape. — A layer of cloth tape thoroughly filled with a rubber compound lapping one-fourth of its width shall be applied over the cloth insulation.

Electrical Tests. — Each and every length of cable shall conform to the specified electrical tests. Braided wires to be tested after twelve (12) hours immersion in water and before the braid is applied; lead-covered conductors to be tested against the sheath with sheath grounded. Multiplex cables shall be tested between each conductor, and the other conductors and sheath or ground in multiple.

Impregnated Paper Insulation. — (*Assoc. Ry. Elect. Eng., 1912.*) The insulation shall consist of a Manila paper applied helically and evenly to the conductor, and then thoroughly impregnated with an insulating compound. The cable shall be pliable and show no tendency to harden injuriously at 32° F. The paper or compound shall contain no acids, alkalis or metallic salts.

The compound shall be applied so as to exclude all air and moisture.

Tensile Strength. — The tensile strength of the paper measured lengthwise before impregnation shall be equivalent to the weight of a strip not less than 20,000 feet long, and its elongation shall be not less than 2 per cent. Acceptance will be based upon the average of six tests on samples selected at random from every order.

Electrical Tests. — Each and every length of cable shall conform to the specified electrical tests. No immersion is required before testing. The potential test to be made between conductor and sheath with the sheath grounded. Multiplex cables shall be tested between each conductor, and the other conductors and sheath or ground in multiple.

Braids. — (*Assoc. Ry. Elec. Eng., 1912.*) Braid shall be of closely woven cotton thread, at least two-ply, thoroughly impregnated with an insulating weatherproof compound and finished with a black insulating compound thoroughly slicked down. The compounds shall be neither injuriously affected by nor have injurious effect upon the braid at a temperature of 200° F. The thickness shall be not less than given in the following table.

Diameter over the insulation, inches	Thickness of braid, inches, not less than
0.160	0.018
0.290	0.028
0.530	0.038
1.000 and over	0.053

For intermediate diameters use next smaller diameter. (Note: The above does not apply to fancy or special braids for fixtures, etc.)

Tests. — A six-inch sample of wire with carefully paraffined ends shall be weighed and submerged in fresh water of a temperature of 70° F. for a period of twenty-four hours. The increase in weight after submersion and removal of surface water shall be not more than 8 per cent of the weight exclusive of copper and insulation before submersion. The compound shall not drip at a temperature of 125° F.

Rubber-filled Cloth Tape. — (*Assoc. Ry. Elec. Eng., 1912.*) The tape shall consist of a cotton cloth not lighter than one pound per four yards 36 inches wide with not less than 56 by 60 picks per inch, thoroughly filled with a rubber compound. The tape shall be applied spirally overlapping not less than one-quarter of its width. The following table gives the maximum width of tape allowed.

Diameter over insulation, inches	Maximum width of tape, inches	Diameter over insulation, inches	Maximum width of tape, inches
2.00	5	0.62	2
1.75	4½	0.50	1¾
1.50	4	0.44	1½
1.25	3½	0.38	1⅜
1.15	3¼	0.31	1⅛
1.00	3	0.25	⅞
0.88	2¾	0.19	¾
0.75	2⅝	0.16	⅝

For intermediate diameters use next smaller diameter.

Sheath. — (*Assoc. Ry. Elec. Eng. 1912.*) Unless otherwise specified the sheath shall have an average thickness of not less than that indicated in the tabulation next following, and the minimum thickness shall in no place be less than ninety per cent of the required average thickness.

Composition. — The sheath shall consist of commercially pure lead for all cables having a core diameter (i.e., internal diameter of the sheath) less than two inches; for cables having a core diameter equal to two inches or more the sheath shall consist of an alloy of lead and commercially pure tin containing not less than one per cent of tin.

Wire Armor. — (*Assoc. of Ry. Elec. Eng., 1912.*) The core of the cable shall be run through a hot asphalt compound, served with a layer of jute yarn, run through hot asphalt again, and then laid with galvanized wire armor.

Size of Armor Wire. — The proper size of armor wire will depend upon the conditions of service; the latitude allowed in the following table represents the difference arising from such difference in service conditions. Unless otherwise specified the armor wire shall be the minimum size.

Internal diameter of sheath, inches	Corresponding thickness of sheath in 64ths of an inch	
	Paper insulation	Rubber or var. cloth insulation
0.00 to 0.29	5	4
0.30 to 0.69	6	5
0.70 to 1.24	7	6
1.25 to 1.99	8	7
2.00 to 2.69	9	8
2.70 and over	10	9

For intermediate diameters use next smaller diameter.

Lay. — The armor shall be applied closely without appreciable space between adjacent wires. The lay shall be from eight to twelve times the pitch diameter.

Finish. — The armored cable shall be run through hot asphalt compound, served with a layer of the best three ply 14 pound hard-twisted jute yarn applied in a close short lay, run through hot asphalt compound, then served with a second layer of three-ply, 14-pound jute yarn, run through hot asphalt compound and finally run through some material to prevent sticking.

(Under certain conditions, the purchaser may find it advisable to specify the omission of the outer jute covering.)

Diameter of cable under jute bedding, inches	Armor wire A. (Steel) W. G.	Jute bedding under armor measured in finished cable, inches
		minimum
0.00 to 0.50	14-13	2/32
0.44 " 0.69	12	2/32
0.63 " 1.00	10	2/32
0.88 " 1.50	8	2/32
1.25 " 2.00	6	2/32
1.30 and over	4	2/32

Direction of Lay. — Successive layers of jute or jute and armor shall be laid in opposite directions. In the case of multiple-conductor cable armored without lead, the outside layer of conductors shall be put on with a right-hand lay. The armor shall be put on with a left-hand lay. The direction of lay is defined as the lateral direction in which the wires run over the top of the cable as they recede from an observer looking along the axis of the cable.

Tests of Armor Wire. — The armor wire shall consist of a galvanized mild steel wire of uniform diameter, free from all cracks, splits or other flaws. Samples shall be taken at random from 10 per cent of the coils to be used, for each of the following tests. At least 80 per cent of the samples shall fulfill the conditions of the tests in order that the whole lot may be considered satisfactory.

Tensile Test. — The wire must have a tensile strength of 50,000 pounds per square inch and an elongation of not less than ten per cent in eight inches.

Galvanizing Test. — Thoroughly clean a sample to remove all dirt and grease, rinse in clean water and wipe dry with a clean cloth or cotton waste. Immerse for one minute in a solution of copper sulphate, rinse in clean water and wipe dry. Repeat this operation until the samples have been immersed

four times. After these immersions no sample shall show any bright deposit of copper. The samples shall be approximately straight and the ends protected with paraffine. The solution shall be saturated with copper sulphate to which an excess of C. P. cupric oxide has been added, shall have a specific gravity of 1.186 at 65°F. and shall be maintained at 60° to 65° F. during the test.

Flexibility Test. — The armor wire shall admit of bending around a spindle of ten times the diameter of the wire and back again without developing cracks of the galvanizing which are visible to the naked eye.

Steel-tape Armor. — (*Assoc. Ry. Elec. Eng., 1912.*) The core of the cable shall be run through a bath of hot asphalt compound, served with a layer of jute yarn spun on with a close short lay, run through hot asphalt compound, armored with a steel tape, armored with a second steel tape, run through hot asphalt compound, served with a layer of one-hundred pound jute yarn with a close short lay, run through hot asphalt compound and finished by running through some material to prevent sticking. Each layer of jute shall be applied in the reverse direction to the adjacent layer. The space between adjacent turns of steel tape shall not exceed one-tenth the width of the steel tape.

Armor Tape. — The tape and jute under armor, after armoring, shall conform to the following table:

Cable diameter before armoring, inches	Maximum width steel tape, inches	Minimum thickness each tape, inches	Minimum jute thickness under armor, inches
0.00 to 0.45	½	0.02	0.06
0.46 to 0.75	¾	0.02	0.06
0.76 to 1.00	1	0.03	0.07
1.01 to 1.40	1¼	0.03	0.07
1.41 to 1.70	1½	0.04	0.08
1.71 to 2.00	1¾	0.04	0.08
2.01 and over	2	0.05	0.09

Cable Reels. — Each reel shall consist of a wooden drum with wooden disks or heads securely fastened thereto.

Bushing. — Each disk or head of the reel shall be provided with an iron plate or cast-iron bushing in the center of which shall be a hole 2½ inches in diameter. The plates or bushings shall be secured to the head by means of bolts or lags through the head.

Covering. — Insulated cable shall be thoroughly covered with burlap before lagging is applied.

Lagging. — When used for insulated cable the reels shall be suitably lagged; when used for bare cable, the lagging of the reel shall be replaced by a burlap covering securely bound to the cable.

Chocking. — Reels shall be properly chocked in the car so that there shall be no movement of reels during transit.

INSTALLATION OF INSULATED WIRES AND CABLES. — For the installation of wires and cables in buildings see articles on *Wiring of Buildings for Light and Power; Wiring of Buildings for Miscellaneous Devices.* Below is given a brief description of modern practice in installing insulated wires and cables on messenger wires and in underground conduit systems. For the construction of the pole lines carrying the messenger wire see articles on *Poles*

for Overhead Lines; Towers, Transmission. For the construction of conduit systems see article on *Conduits and Conduit Lines.* See also the articles on *Distribution Lines* and *Transmission Lines.*

Messenger Construction. — The messenger wire is erected in the same manner as an ordinary line wire; see article on *Transmission Lines.* A "leading-up" wire is stretched from the bottom of one pole to the messenger wire on the starting pole, forming an incline on which to pull up the cable. A pulling rope is then fastened to the end of the cable by means of a cable grip and carried alongside of the messenger to the point where the cable is to reach, thence through a snatch-block down to the terminal pole to a second block at the bottom and thence to a capstan, winch, locomotive or whatever is to be used for pulling. Either temporary rollers should be provided on the poles over which the rope runs, or the rope should be suspended from the messenger by wire hooks. The cable is then slowly drawn up the inclined wire and along the messenger, attaching temporary carriers to the cable as it is paid out and hooking them over the messenger to carry the weight of the cable. Linemen must be stationed on each pole to pass these carriers around the messenger clamp or insulator. The final suspension of the cable may be accomplished in either of the following ways: (1) When the end of the cable arrives at the beginning of the last span, the lineman on each pole replaces the temporary carriers by permanent hangers, spacing them regularly along the cable, so that when the last span is pulled, all the hangers will be in place. (2) When the cable has been pulled all the way, a lineman rides along the messenger wire in a carriage replacing each temporary carrier by a hanger. This plan is preferable as the hangers may be attached more tightly to the messenger wire, and are less likely to slip on the cable.

Installation of Cables in Ducts. — The conduit system having been constructed, it must be prepared for the reception of the cable by being cleaned out or rodded as described in the article on *Conduits and Conduit Lines.*

If there are several ducts available, the choice of the particular duct to be used should be governed by the following considerations: 1. Avoiding unnecessary crossings of cable in the splicing chambers, substations, etc; 2. Avoiding the obstructing of empty ducts; 3. Keeping the cables cool; and 4. Keeping d-c. cables away from others. The following statement in the catalogue of the A. S. & W. Co. is pertinent with regard to keeping the cables cool. "Usually the coolest and best heat-radiating ducts are those located at the lower corners of the system, next are those nearest to the outside of the system and lastly the middle and top ducts which not only take up heat from the lower cables, but must dissipate heat through adjoining ducts. Attention to these points when planning a new system may prove very profitable in the end."

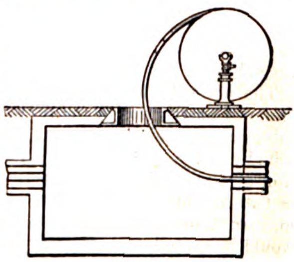

Fig. 13.

The next step is to set the cable reel on the shaft of a pair of wheels of slightly greater diameter than the reel itself or on jacks and raise it slightly above the ground, taking care to locate it as shown in Fig. 13, so that the cable will unreel into the manhole without making a reverse bend.

Fig. 14.

The pulling rope having been left in the duct after rodding, the cable is unreeled sufficiently to bring its end close to the mouth of the latter and a wire pulling grip (Fig. 14) is drawn over its end. The

end of the grip is hooked to the rope and the rope pulled from the other end. Fig. 15 shows an arrangement of pulleys for guiding the pulling rope. The pulling may be done by capstan, winch, motor truck, horse or by hand, depending upon the size and amount of cable to be pulled, and upon local conditions. The cable should be carefully guided into the duct so as to avoid sharp bends and abrasions, and a small quantity of grease may with advantage be spread over the cable as it enters the duct. R. J. Robb (*Journ. I.E.E., 1911, Vol. 47, p. 350*) says that 112 pounds of petroleum jelly is required per mile of cable. It is also necessary to cover the edges of the duct with pieces of lead to prevent abrasion of the cable as it passes into the mouth of the duct.

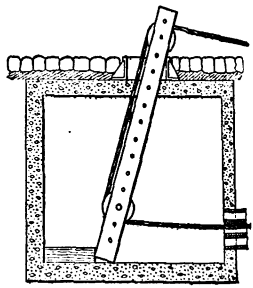

Fig. 15.

Protection of Cables in Splicing Chambers. — (*See also article on Conduits and Conduit Lines.*) Wherever there are several large cables in a splicing chamber, there is always danger that a burn-out of one cable will involve some or all of the remainder. Hence it is usual to protect such cables by means of one or more of the following methods:

1. Concrete shelves,
2. Open-face conduits,
3. Cement coating with ¼-inch rope bond,
4. Asbestos tape saturated with silicate of soda,
5. Asbestos tape covered with soft steel-tape armor,
6. Asbestos rope,
7. Split tile duct.

Methods Nos. 1 and 2 are applicable only to chambers containing few cables. No. 3 has given good results in many cases, but the cement is liable to crack and fall away from the cable unless carefully bonded. On the other hand, the location of a burn-out is plainly indicated by the cement covering being blown off. No. 4 combined with No. 5 is very generally used and gives very satisfactory results. No. 6 is but little used. No. 7 is very satisfactory, but is very clumsy, and cannot be used where there are many cables in the chambers.

The necessity for such protection (according to the Committee on Underground Construction of the N. E. L. A., 1911) is equally great with low-tension cables as with high-tension cables, for, while a breakdown of the insulation of a high-tension cable is often attended with a violent explosion and the generation of a very high temperature, the duration of the trouble is limited to one or two seconds; whereas in the case of a short circuit on a low-tension cable, it may continue to burn with a considerable flame for several minutes, which would be quite long enough to damage adjacent unprotected cables.

In the case of direct-current feeders for electric railways, where the return is grounded, the danger of burn-outs spreading is much greater than with the insulated lighting systems referred to in the N. E. L. A. report. This subject is treated at greater length in the author's *Electric Power Conductors*, from which the following is quoted: "If it is necessary to put direct- and alternating-current cables in the same duct line, it is well to isolate the direct-current cables as much as possible in the splicing chambers. The racks on which direct-current cables are supported should not be in metallic contact with other racks. If, however, this is unavoidable, the cables should not lay directly on the racks, but on insulating pads or blocks."

Jointing Insulated Conductors. — (*See also article on Wires and Cables, Bare.*) Having selected the corresponding cable ends, they should be inspected for mechanical defects along the entire exposed length and bushings placed over them at the ducts so that the sheath will not be cut by the edges of the conduits. The cables should then be bent until the ends overlap, the bends being of ample radius throughout, and the position of the cable such that the joint, when completed, will not have to bear any elastic stress or weight.

Drying Out Cable Ends. — In the case of paper or cambric insulated cables, the ends should be examined for moisture before they are finally cut short and if any exists or is suspected, heat should be applied to the sheath, beginning at the duct end and slowly working to the open end. This is usually done with a gasoline torch but sometimes by pouring on hot insulating compound.

Overlap. — This operation having been completed, the cable ends are cut so as to leave an overlap, depending upon the method of joining the conductors (*see below*) and upon the number of separately insulated conductors in the cable. If the cable has but a single conductor, and a butt joint is to be used, the overlap should be merely sufficient to allow for cutting off the ends, whereas if an interlaced joint is contemplated, the overlap should be greater by about 3 or 4 times the diameter of the conductor. In the case of multiple-conductor cables, the separate joints of which must be staggered, the overlap should be correspondingly greater.

Removal of Sheath. — The next operation is to cut off a sufficient length of lead sheath to permit the joint to be made. This length may be judged from the size of the sleeve to be used (*see below*). The operation is performed with a chipping knife and hammer, or with a special tool designed for the purpose, and the greatest care should be exercised to avoid cutting the insulation to the slightest degree. It is usual to make a cut around the sheath and gradually increase its depth until the lead is cut through. The lead must then be cut lengthwise from the circular cut to the end, injury to the insulation being avoided by holding the knife tangent thereto. The lead may then be pulled off with a pair of pliers and loose particles carefully removed. In the case of high-tension cables the ends of the lead should then be turned up slightly to a bell-mouth shape by means of a special tool.

Putting on Lead Sheath. — Before jointing the conductors, the lead sleeve should be slipped over one of the cable ends and pushed out of the way. The ends of the sleeve should have been previously scraped for a length of about a couple of inches along the outside and the cleaned surfaces smeared with tallow.

Removal of Insulation. — The next step is to cut back the insulation for a length between ¼ and ½ inch greater than half the length of the connector to be used. In the case of multiple-conductor cables having a belt, the belt must be cut back sufficiently to expose all the joints, the greatest care being exercised to avoid cutting the inner insulation in doing so.

Jointing the Conductors. — The next process is to prepare the conductor or conductors for jointing. The most usual type of joint is made by butting the ends of the conductors and enclosing them in a cylindrical copper connector. The conductors are first cleaned with gasoline and then tinned by pouring molten solder over them, using tallow for flux. All burrs should be removed with a file and the ends smoothed so that they will butt together perfectly. The connector is then put over one conductor end and the other end slipped in until the two ends butt. Solder is then poured over the joint until it is thoroughly saturated, when the surplus is wiped off so as to leave no sharp projections.

Connectors. — The connector should have a cross-section not less than that of the conductor and a length in accordance with the following table.

A length of 2¾ inches is recommended by a Committee of the N. E. L. A. (1911) for high-tension cable joints.

From points ½ inch back from each end, it should be pencilled down to thin edges at the ends, and it should be split the entire length on one side.

Size of conductors	Length of connector, inches
0 to 000 B. & S.	1-2
0000 B. & S. to 1 million Cir. Mils.	2½-3
1¼ million to 2 million Cir. Mils.. .	3½-4

Jointing Stranded Conductors. — While the connector joint is by far the most common, stranded conductors may be joined by cutting the wires alternately long and short, and fitting the two conductor ends into one another. The joint is then bound with small wire. Stranded conductors are sometimes joined by cutting the wires of successive layers alternately long and short, and telescoping the ends into one another. Yet another method is to lay strips of flexible copper braid longitudinally along the butted conductors and bind them securely with copper wire. In any case, the joint must be saturated with solder and wiped, as described above.

Insulation of Joint. — The next step is to insulate the joint. The usual process is to cover it with a tape of similar material to the remainder of the cable insulation, although this method is not universal. If of oiled paper or varnished cambric, the tape should be cut on the bias. Assuming this to be the process, the cable insulation is tapered gradually to the conductor, by means of a sharp knife, leaving about ½ inch between it and the connector. After this has been done, the exposed insulation, if paper, is to be dried by pouring over it melted paraffin heated to a temperature of 125° C. Narrow strips of tape should first be wrapped in the space between the insulation and the connector until this space is built up to the diameter of the connector. Wrapping should be continued back and forth in the space between the two ends of the original paper insulation until it is built up to the level of this insulation. The tape is then wound on until a thickness about 40 per cent greater than that of the cable insulation is reached, the tape running up the sloping part of the insulation until firmly attached to it.

In the case of three-conductor high-tension cables the wrapping should commence at a point on the covered conductor 3 inches from the outer belt and extend to a corresponding point at the other end. The wrapping is then continued back and forth, stopping each successive layer ½ inch short of the end of the preceding layer. In applying the tape, each turn should be drawn tight to exclude air and should overlap the preceding turn by two-thirds of its width. It is important that the tape should be applied tightly and evenly. In the case of rubber tape the tension should be such as to stretch it to about half its width. In this process care must be taken to have everything perfectly clean.

"Boiling Out." — Where cotton or linen tape is used, each layer must be "boiled out" by pouring hot compound over it until all the moisture is expelled and the tape wrapping is thoroughly saturated. Before applying the compound the jointer should assure himself that it is *not* hot enough to ignite a piece of paper dipped in it; otherwise the tape is likely to be charred. This should be done before entering the splicing chamber, as the accidental ignition of a pot of compound is dangerous in such a confined space.

Vulcanizing. — Where rubber tape containing sulphur is used, it should be partially vulcanized by the application of heat from a spirit lamp, care being

taken to apply the heat evenly and to avoid burning the insulation. This process is usually complete in about one minute with conductors up to one-half inch diameter.

Spreaders for Three-conductor Cables.— In the case of three-conductor cables, after all the conductors are joined and insulated as described, a roll of tape ½-inch diameter is inserted between them at the center of the joint to serve as a spreader. A band of tape is then wrapped around all three conductors to such a diameter that the whole will slide nicely into the lead sleeve, as shown in Fig. 16.

Use of Insulating Tubes. — Another way of insulating joints is to slip an insulating tube over the conductors before soldering and bring it over the joint when the latter is completed. In order to get the sleeve out of the way during soldering, it must be large enough to slip easily over the insulation. Such tubes are made of prepared paper, varnished cloth, or micanite. The jointed conductor should first be wound with cotton tape up to the level of the original insulation, "boiled out" as described above, and then the sleeve slipped on. A further "boiling out" with hot compound completes the job. In the case of belted multiple-conductor cables, in addition to the insulating tube over each conductor a large tube must be slipped over the belt before splicing the conductors.

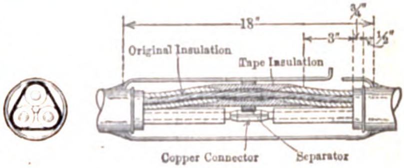

Fig. 16.

Owing to the absence of convolutions of tape and to the thorough impregnation of the tubes at the factory, this type of insulation is claimed to be more reliable than tape.

English Practice.—A type of joint used largely in England for multiple-conductor cables, has the conductors separated from one another by an insulating spreader or separator, which may be of ebonite, china or similar material. The shrinkage of solid compound gives rise to air holes near the conductors, with consequent low dielectric strength. By insulating the cores separately with insulating tapes before the compound is run in, this trouble can be avoided, but it is better to use a viscous compound which never sets (Vernier). This type of joint has two serious defects, 1st, breakdown is likely to occur on account of defects of the separators or on account of moisture on their surfaces; 2nd, a longitudinal pull of the cable, such as is likely to arise when the cable shrinks in cold weather, puts the separators in compression and may stress them unduly.

Lead Sleeves. — The joint having been insulated, the lead sleeve should be brought symmetrically over it, and the ends beaten down into contact with the sheath, taking care to make the sleeve concentric with the cable.

The sleeve and sheath are then joined by pouring solder over the ends from a ladle and wiping the joint with a cloth. This process should be continued until perfectly air-tight joints are obtained, the under side being examined for defects by means of a hand mirror.

When the sleeve is well wiped on, two small holes should be made in the top of it and hot compound poured in one hole until it appears at the other. If any frothing appears, the compound should be poured in one hole and allowed to escape from the other until this defect ceases. The joint should then be allowed to cool for about an hour, and if then the compound has settled, more should be added until the sleeve is full. The sleeve is then closed by soldering

The following data on lead sleeves are given by the Standard Underground Cable Co.

DATA ON LEAD SLEEVES

	Outside diam. of cable, mils	Inside diam. of sleeve, inches	Length of sleeve, inches	Gals. of compound per joint	Wiping solder per joint, lbs.
Single-conductor, light and power, up to 6600 volts.	Up to 550	1	8	0.05	0.9
	551–950	1½	10	0.1	1.7
	951–1350	2	12	0.2	2.8
	1351–1750	2½	12	0.3	4.2
	1751–2150	3	14	0.5	5.5
	2151–2550	3½	14	0.6	6.8
Single conductor, light and power, above 6600 volts.	Up to 550	1	10	0.05	0.9
	551–950	1½	12	0.1	1.7
	951–1350	2	14	0.2	2.8
	1351–1750	2½	16	0.4	4.2
	1751–2150	3	18	0.6	5.5
	2151–2550	3½	18	0.8	6.8
Multi-conductor, light and power, all voltages.	Up to 800	1½	14	0.2	1.5
	801–1200	2	16	0.25	2.5
	1201–1600	2½	16	0.35	3.7
	1601–2000	3	18	0.6	5.0
	2001–2400	3½	18	0.8	6.3
	2401–2800	4	18	1.0	7.6
	2801–3200	4½	20	1.4	8.3

small patches of lead over the holes. When the joint has thoroughly cooled and solidified, it may be pushed gently into its permanent place.

Compounds for Filling Lead Sleeves. — Various compounds have been used for filling the sleeves, such as paraffin wax, G. E. No. 227 compound, voltax, ozite, etc. Paraffin does not adhere to smooth surfaces and has an excessive contraction coefficient, causing voids which have a dielectric strength lower than ordinary air. The Commonwealth Edison Co. of Chicago uses a compound developed by the engineers of the company. It is poured in at a temperature of 150° C.

A good compound should have a high melting point, adhesiveness, high dielectric strength, low coefficient of contraction and should not be brittle at ordinary temperatures.

Stamping the Joint. — After the joint is completed the jointer should stamp his initials at each end of the sleeve.

Taped Joints. — Where the cable has no lead sheath, but is merely braided, it is usual to finish the joint with friction tape.

Terminals. — Conductors may be soldered to lugs or terminals or they may be clamped mechanically by means of a Dossert or similar connector.

In the former case the insulation is cut from the end of the conductor, which is then brightened by scraping or sandpapering and smeared with soldering flux. The conductor is then tinned by plunging into molten solder. The lug

must also be tinned internally and heated so that it will hold some solder in the molten state. The conductor, also heated above the melting point of solder, is then pushed into the lug and the latter cooled by the application of wet waste. When cool the shreds and globules of solder are filed off and the surfaces brightened with sandpaper. Some jointers prefer to hold the lug in the molten solder until it attains the same temperature as the latter. In this case, if the lug has been previously treated with flux, its outside as well as its inside surface will be tinned and it will make better contact with its accompanying lug or terminal. If, however, the copper or brass surface is desired for appearances, it may be preserved by coating the outside of the lug in a light oil of high flash point, before dipping it into the solder.

In either case it is advisable to wrap the end insulation in a rag previously wrung out in cold water to prevent it being melted or charred.

Grounding Sheaths. — The conductors of high tension cables induce electrostatic charges on the sheaths, often raising the latter to dangerously high potentials. It is, therefore, customary to ground the sheaths of cables at suitable points in order to carry off the "static," as these induced charges are called. The sheaths of low-tension cables do not have to be grounded to drain off static electricity. The sheaths of direct-current railway feeders which are used in conjunction with a grounded return system should, however, be grounded to the negative return system, except when the tracks have insulated sections for automatic block signals, in order to afford a low-resistance path for a short-circuit current. Unless this is done, the escaping current will return through devious paths, inflicting damage without attaining sufficient strength to trip the station circuit breakers.

BURN-OUTS OR PUNCTURING OF INSULATION. — Cable burn-outs may be caused by mechanical injury, exposure to excessive heat or cold, by chemical deterioration, or by transient high-voltage phenomena.

Burn-outs Due to Mechanical Injury. — Paper insulation differs from rubber and varnished cambric in depending upon the integrity of the lead sheath which incloses it. Hence in the case of paper-insulated conductors, a puncture of the lead sheath will sooner or later result in a burn-out even though it may take a week or longer for the moisture to penetrate the insulation sufficiently to accomplish this. (*Burch, Trans. A.I.E.E., 1903, vol. 22, p. 433.*) The moisture-resisting qualities of paper insulation are further treated above in the section on *Tests and Inspection.*

Mechanical injury often occurs in the process of installing underground cables. A slight projection in a duct will cut a groove in the lead sheath, thereby reducing its effective thickness and rendering it liable to crack open. The bending of cable in splicing chambers may crack the insulation, especially if tightly wound paper insulation is used. A loosely insulated cable is also liable to injury because bending will flatten the cable, compress the insulation in one direction and flare it out in the other, causing voids or air spaces between the layers, which under the influence of high voltages will cause electric discharges, heating, ozone and consequent chemical action. Mechanical injury after installation may be due to settlement of the conduit line, to careless stepping upon the cable, to vibration setting up crystallization of the lead sheath, etc.

Exposure to alternate heat and cold leads to expansion and contraction which may introduce mechanical stresses into the insulation and thereby injure it. Excessive heat (120 to 150° F.), such as would result from direct exposure to summer sunlight, is likely to dangerously reduce the insulating qualities of varnished cambric and to a less extent that of oiled paper. A higher degree of heat (200° F.), such as would occur in the proximity of steam pipes, has the effect of making rubber insulation become brittle.

Chemical deterioration may be due to electrolysis (q. v.) or merely to ordinary chemical reaction between the sheath and the material in contact with it, the former cause being the more common.

Burn-outs Due to Static Discharges. — Failure of high-tension rubber-insulated conductors is sometimes due to electrostatic discharges from the charged conductor to its supports, the irregular potential gradient giving rise to local static discharges with consequent formation of ozone and oxidation of the rubber.

Burn-outs Due to Imperfect Manufacture or Splicing. — Insulated conductors also burn out because of defects of manufacture or of splicing. The former class of defects is happily rare, but dirt, moisture and jagged edges of metal are frequently responsible for the failure of joints, especially on high-tension cables.

Transient High Voltages and Currents. — "Surges," i.e., transient high voltages and heavy currents, are sometimes responsible for very serious cable failures, such as described in *Trans. A.I.E.E., Vol. 24, p. 297.* To determine the origin and cause of high-voltage disturbances, so as to be able to guard against their recurrence, the most important thing seems to be to very carefully observe and record all the details of the phenomena, even those which appear unessential. The existence of static (i.e., high-voltage discharges of small currents) on switchboards, lines, etc., and the existence of voltages and currents different from those which may be expected require special attention. Either of these is sufficient to raise the suspicion of some dangerous fault in the system or some dangerous arrangement of apparatus, which requires consideration. The severity of the phenomena depends almost entirely upon the power momentarily available in the system and very rapidly increases with the size of the generating stations (*C. P. Steinmetz*).

After considering the likelihood and severity of such potential disturbances, P. Junkersfeld and E. Schweitzer reached the following conclusions with respect to their influence upon the use of high-tension cables.

1. Where local and commercial conditions justify, pressures as high as 25,000 volts can be satisfactorily used even for systems aggregating as much as a hundred miles of cable. No single line of such a system would be much longer than twenty miles. If higher voltages are needed to meet operating requirements and can be justified commercially, special construction will be necessary to overcome limitations in paper, rubber or varnished-cambric insulation, and also in the standard forms of underground conduit or subways used in this country.
2. On comparatively short lengths, underground or under water, as a part of a long overhead transmission line, cables operating at 40,000 volts can be used.
3. Potential rises of 50 per cent and 100 per cent are not uncommon in large underground cable systems, although this fact may not always be manifest, due to the high factor of safety in the insulation.

Occurrence of Cable Burn-outs. — The following table gives the number of cable burn-outs on some important cable systems. In each case the cables were three-conductor cables and were operated at 25 cycles.

REPAIRS. — The principal work of repairing cables consists in replacing lengths, for details of which see above under *Installation*. Sometimes a burn-out in a splicing chamber merely necessitates the insertion of a short length of cable, in which case two splices are necessary.

Lead-sheathed cable, which has been removed from ducts after having been in service, may often be releaded and made practically as good as new. The sheath is first stripped from the cable by passing the latter continuously over

a pair of wheels between which a stationary knife is set, as shown in Fig. 17. The knife cuts nearly through the sheath, which is then pulled off by means of special tools. The core is re-saturated and a new sheath put on in the usual way.

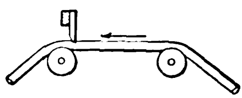

Fig. 17.

COST.—The cost of cables depends upon the price of their constituent metal, insulation, protection, sheathing, etc., and upon the degree of congestion in the factories. As rubber, copper and aluminum vary greatly in price from time to time, it is useless to give any specific cable costs, but the relative cost of different size cables of the same type and for the same voltage usually follows a curve such as shown in Fig. 18; the actual costs given in this curve refer to double-braided 30% Para rubber insulated cables and are approximate only. The cost per foot C, except for small conductors, practically follows the equation $C = A + Bx$ where A and B are constants depending upon the type of cable and the cost of materials and x is the cross-section of the conductor in circular mils. A curve of the same shape is applicable to multiple-conductor cables.

Life.—The life of cables depends so much upon the type, excellence of manufacture and conditions of service, that specific figures are of little use. An

average life of 20 years is suggested by A. W. Welch, provided the cables are not disturbed and are properly protected from electrolysis. Vernier says from 20 to 30 years. Fernie says that low-tension rubber-insulated cables in wet ducts last only 7 or 8 years. (*See article on Depreciation.*)

[W. A. Del Mar.]

WIRES, RESISTANCE. *(See also Electromagnet Windings; Resistance and Conductance, Electric; Rheostats and Resistors; Wires and Cables, Bare; Wires and Cables, Insulated.)* Metals and alloys having high specific resistance or low temperature coefficient of resistance are largely used for resistors. Some of the principal metals used for this purpose are listed below. They can usually be obtained in the form of wires, ribbon or sheets. The data given for Nichrome, Climax, Advance, Therlo, Yankee Silver, Ferro nickel, Monel Metal and Nickel were supplied by Mr. L. O. Hart of the Driver Harris Wire Co. The data on Krupp metal were supplied by T. Prosser and Son, those on Calido and Ideal materials were supplied by the Electrical Alloys Co., and those on Excello, Ia Ia, and Superior resistance metals were taken from the 1914 catalogue of Hermann, Boker & Co.

Advance. — This material is a copper-nickel alloy, containing no zinc. It is uniform in its composition and constant in its resistance under all conditions of service. It is especially recommended for measuring instruments and apparatus in which the wire is subjected to repeated heating and cooling.

Calido. — This is a high percentage nickel chromium alloy containing a small percentage of iron. The melting point is about 1550° C. It is recommended for electrically heated devices.

Climax. — This is a high resistance nickel steel alloy. It is especially well suited for use in rheostats. It is one of the cheapest resistance metals.

Excello is adapted for use in electric heating devices.

Ferro-nickel. — This alloy has a high current-carrying capacity, on account of its low specific resistance. As it will rust, it can only be used where it is not attacked by moisture.

German Silver.— This is an alloy of copper, nickel and zinc. The "grade" of the wire designates the percentage of nickel. The 18 per cent grade is the most common. The resistance of any particular grade depends upon the degree of annealing; hard wire is slightly higher in resistance than soft. German silver was for many years the only resistance alloy obtainable, but it is now being generally displaced by materials of the same specific resistance but of superior qualities.

Ia Ia is recommended for use in instruments and electrical devices where a low temperature coefficient is desired.

Ideal. —This is an alloy of nickel and copper, and contains no zinc. The manufacturers state that its temperature coefficient is "nil." It may be used at an incipient red heat of 520° C. It is adapted for resistors and measuring instruments.

Krupp Metal. — This is a special grade of nickel-steel adapted for resistors.

Manganin. — This is a material developed by the Reichsanstalt, for use in instruments and standards. The alloy which was shown to be the best for ordinary purposes is one containing 85 per cent of copper, 12 per cent of manganese and 3 per cent of nickel.

Monel Metal. — Monel metal contains approximately three parts nickel to one of copper. In smelting and refining the ore from which monel metal is made, the nickel and copper are not separated, and, therefore, appear in the finished alloy in the same relative proportions. The treatment of this ore consists merely in eliminating the impurities, excepting a small percentage of reduced iron. As a result the metal is tough, strong, as non-corrosive as pure nickel, and is the same in appearance; whereas nickel, as a pure metal, is relatively expensive, owing to the difficulty of isolating it. This alloy is produced at a cost which permits favorable competition with German silver, etc. The

TABLE I. — PROPERTIES OF RESISTANCE METALS

Material	Maximum working temp., °C.	Microhms per $cm.^3$ at 20° C. ρ	Temperature coefficient per ° C.: α_{20}	Specific gravity: δ	Tensile strength, lb. per sq. in.	Linear expansion coefficient per° C.

Therlo (*a*)	100	46.7	0.000006	8.15	....	19.4×10^{-6}
Yankee silver	480	33	0.000154	8.6	....	15.9×10^{-6}

(*a*) **Thermo-electric Power** of these metals with copper, in microvolts per ° C. is approximately: Advance, 40; German silver, 20 to 30; Ideal, 45 (M.I.T. tests); Manganin, 1 to 2; Nickel, 19.5; Therlo, 0.3 (*see also Pyrometers, p. 1153*).

(*b*) 30 per cent German silver has substantially the same properties as Advance metal.

(*c*) The melting point of Excello is 1500° C.

resistance varies somewhat in different lots, and according to temper. The variation is, however, no greater than that of 18 per cent German silver.

Nichrome. — This alloy is practically *non-corrosive*, has an extremely high melting point (about 1550° C.) and is far superior to nickel in its ability to withstand high temperatures. It is especially recommended for use in electrically heated appliances and resistance elements generally where extreme conditions are encountered.

Nichrome II. — This alloy is strongly resistant to oxidation. It has been especially developed for use in carbon combustion furnaces, and other laboratory furnaces where the more extreme temperatures are to be met.

Nickel. — Due to its high temperature coefficient nickel is very efficient for use in resistance thermometers and owing to its non-corrosive qualities it may be employed for rheostats where acid fumes are to be met with.

Superior is recommended for use in rheostats, arc lamp resistances, etc.

Therlo. — An alloy of copper, manganese and aluminum for work where low thermo-electric effect against copper is demanded. Compared with manganin, this alloy gives a higher specific resistance, does not oxidize so fast, and is more stable in its electrical and mechanical behavior. This material is especially suitable for shunts. Temperature coefficient is + 0.0000031 per 1° F.

Yankee Silver. — This is a new alloy with most of the qualities of "18 per cent German Silver." It will withstand repeated heating and cooling, and often gives satisfactory service where German silver fails.

TABLE II. — RESISTANCE, WEIGHT AND CURRENT-CARRYING CAPACITY OF WIRES

$$\text{Resistance, ohms per foot at } 20^\circ \text{ C.} = \frac{K\rho}{1000},$$

where ρ is the resistivity of the metal in microhms per centimeter cube, taken from Table I, and K is given in the table below.

$$\text{Weight, pounds per foot} = \frac{H\delta}{1000},$$

where δ is the specific gravity of the metal, taken from Table I, and H is given in the table below.

$$\text{Current for given temperature rise, amperes} = \frac{10\, I_0}{\sqrt{\rho}},$$

where ρ is the resistivity of the metal in ohms per centimeter cube, taken from Table I, and I_0 is given in the table below. This formula is approximate only. For insulated wire wound in coils of several layers see article on *Electromagnet Windings*.

WIRING OF BUILDINGS FOR LIGHT AND POWER. — (*See also Distribution of Electric Energy; Distribution Lines; Transmission Lines; Wires and Cables; Wiring of Buildings for Miscellaneous Devices.*)

The following is a brief table of contents of this article:

General Requirements. — Wires and fittings designed to conduct electricity in a building should be selected as to size and insulation and installed in such a manner that: (1) the attending fire risk and the possibility of an electric shock to the inhabitants shall be a minimum; (2) the electric power efficiency of the system shall be reasonable; (3) the voltage at the receiver shall approximate the rated voltage of the receivers and shall remain sensibly constant; (4) the mechanical arrangement of the system shall be simple and convenient for inspection and use; (5) the conductors shall be mechanically protected from external injury; (6) the service shall not be interrupted under normal load; (7) the cost of the materials, labor of installation and replacement due to depreciation shall not be excessive, and (8) the entire wiring system shall conform to the rules and regulations of any authority having jurisdiction over the building in question.

SYSTEMS OF WIRING. — For direct-current and single-phase distribution the two-wire system (Fig. 1) and the three-wire system (Fig. 2) are

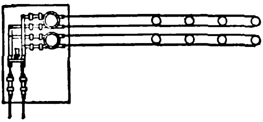

Fig. 1.

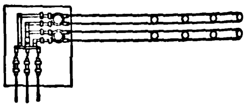

Fig. 2.

employed. For two-phase distribution either three of four wires are used. For three-phase distribution three wires are usually employed, although a fourth or neutral wire is sometimes installed. Fig. 3 shows typical methods of controlling a group of lamps from two or more switches.

Direct-current and Single-phase Distribution. — In direct-current or single-phase alternating-current circuits, the two-wire or the three-wire system is used. The two-wire system is used for the greater part of interior wiring, the three-wire system being used chiefly for feeders and mains. The three-wire system possesses the advantage over the two-wire system that for the

same power transmitted at the same efficiency to receivers of the same voltage, the three-wire system requires less weight of conductor. The neutral wire of a three-wire system is usually of the same size as either outside wire, the saving in copper over the two-wire system then being 5/8 or 62.5 per cent (*see Distribution of Electric Energy*). In some cases, buildings are wired with the three-wire system in which the neutral wire is made twice the size of either outside wire so that if necessary, the system may be operated either as a two-wire or a three-wire system; in the former case the two outside wires are connected in parallel. Power may then be supplied to the building from a local two-wire source of supply (isolated plant in the building) or from an emergency three-wire street service.

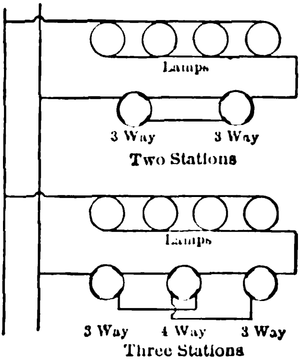

Fig. 3.

In this case wires of such size would be used as would give normal efficiency and regulation when used as a two-wire system; the loss when used as a three-wire system would then be only half as great.

The first cost of a three-wire system may not be less than that of a two-wire system because of the increased cost of the fittings, insulation and the labor of installation. The three-wire system is not as simple as the two-wire system, and is subject to more disturbances unless the load is kept balanced. Some electric power companies limit the power which they will supply to a two-wire system and in such cases in new installations buildings taking power above the two-wire limit must be wired with the three-wire system. The two-wire system is used for either lighting or power loads while the three-wire system is used for either lighting or mixed lighting and power loads, motors in the latter case being connected between the outside wires.

Two-phase and Three-phase Distribution. — For distributing two-phase alternating currents, either three or four wires are employed. A four-wire two-phase system may be treated as two separate two-wire systems, which cannot in any case be connected in parallel. A single wire 41 per cent larger than either of the wires it displaces may be substituted for any two of the wires of the four-wire two-phase system thus making a three-wire two-phase system. Either three or four wires may be used for two-phase lighting or power loads.

Three wires are usually employed on three-phase alternating-current circuits supplying power to lighting or power loads. If the neutral is accessible, a neutral wire may also be used, making a four-wire three-phase system for lighting loads, the lamps being connected between any outside wire and the neutral wire.

STANDARD VOLTAGES FOR LIGHTING AND POWER LOADS. — On all standard lighting loads the voltage across the lamps ranges from 100 to 125 volts in accordance with the rating of the lamps. In a few cases, lamps rated between 200 and 250 volts are used with the corresponding voltages. The voltage between the service wires of a constant-current series-arc or series-incandescent lamp system must not be greater than 3500 volts, the maximum voltage for inside work allowed by the National Electrical Code (see p. 1951.) Constant-current systems are used chiefly in lighting large areas as in mills, factories, armories, etc. On power loads standard voltages of approximately 110, 220 or 550 volts are used depending on the magnitude of the load supplied.

STANDARD FREQUENCIES ON ALTERNATING-CURRENT CIRCUITS. — Alternating currents are usually supplied to lighting loads at a frequency of 60 cycles and to power loads at 25 cycles. In some cases, a frequency of 40 cycles is used when the lighting and power loads are of about the same magnitude.

PRELIMINARY LAYOUT OF THE WIRING SYSTEM. — If power is to be supplied to the building from some outside source, the service entrance must first be located from plans or by an inspection of the building itself. In most cases, service entrances are made in the basement, although first-floor entrances may be substituted when basement entrances are impracticable. In overhead-service connections, the service wires are usually run in conduit on the outside of the building from the point where the wires are attached to the building to the service panel-board. In underground-service connections, the service wires are run in conduit from the street mains through the basement walls. In the latter case, the conduit should be tightly closed at the outlet to prevent gases from entering the building. Fig. 4 shows two types of service connections.

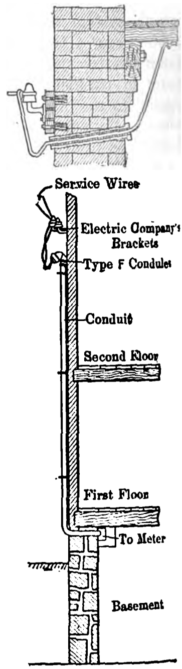

Fig. 4.

Location of Panel-Board. — The service panel-board should be placed securely in an accessible location and should contain space for the service cut-outs, service switch and meter. When power is supplied from within the building, the switchboard of the power plant must be located as a starting point in the design of the feeder system.

Location of Outlets, Switches, etc. — Outlets, control switches and cut-out cabinets should then be located throughout the building. Great care must be exercised in locating outlets and control switches in such positions as to accommodate the receiving devices planned for the building. Cut-out cabinets, which constitute the local distributing centers, should be located as near as possible to the dependent receiving devices and should at the same time be easily connected by feeders to the main switchboard. Fig. 5 shows a riser diagram and Fig. 6 a diagram of the wiring for one floor of an office building.

Number of Feeders. — Having located the outlets, control switches, distribution centers and the main switchboard, a feeder system must be planned to suit the conditions under which the system is to operate. The number of feeder sets required depends upon: (1) the power taken by the receiving devices; (2) the degree of control desired at the main switchboard; (3) the number of receiving devices which may rely upon one set of feeders; (4) the desired uniformity of voltage at the receiving devices, and (5) the character of the receiving devices. If the total current supplied to the building is roughly calculated and is found to exceed 650 amperes (the allowable carrying capacity of a 1,000,000-circular-mil rubber-insulated conductor), more than one set of feeders should be used, since it is impracticable to install feeders larger than one inch in diam-

§ Kind of service wanted ascertained by symbol to which line connects.

eter. In fact, in most cases, it is not considered good practice to install feeders larger than No. 0000 B. & S. gauge (0.46 inch in diameter). Unless controlled by remote control switches, separate feeders must be installed from the switchboard to receiving devices which are controlled at the main switchboard.

If a single set of feeders is used on a lighting load, the possible extinction of all the lights in a building by an open circuit in the main feeders may cause a panic; on a power load an interruption of all the machinery for any length of time may cause a considerable loss of money. To avoid such a discontinuance of the service, it is customary to connect separate feeders to sectionalized parts of the load, so that the entire load may not be interrupted at one time.

The voltage at receiving devices may be made more uniform by the use of separate feeders than by the use of one set of feeders, except when a single set of feeders may be run to a distributing panel to which branch feeders of nearly equal length are connected. When the power taken by certain receiving devices varies extensively and rapidly, the voltage at all other devices connected to the same feeder will vary accordingly, and in such cases lamps must be connected to separate feeders to avoid undesirable flickering.

Wiring Diagram. — After deciding upon the number of feeders to be used in any installation, a diagram should be made showing the location and length of all feeders and branch circuits. When the wiring system is sectionalized, each section should be treated by itself as a complete system. Figs. 5 and 6 are typical wiring diagrams for an office building.

WIRING CALCULATIONS. — The proper size of wire for any feeder is determined by three factors: (1) mechanical strength; (2) current-carrying capacity, and (3) the allowable potential drop in the feeder.

Minimum Size of Wire. — The National Electrical Code specifies No. 14 B. & S. (A.W.G.) as the minimum allowable size for all classes of wiring, except that in fixture work and for pendant cords wires as small as No. 18 B. & S. may be used.

Current-carrying Capacity. — The following table, from the National Electrical Code, gives the allowable carrying capacity of copper wires and cables of 98 per cent conductivity, according to the standard adopted by the American Institute of Electrical Engineers, and must be followed in placing interior conductors. See also *Wires and Cables, Insulated.*

....	....	....	2,000,000	1050	1670

* For insulated aluminum wire the maximum allowable current is 84 per cent of that given in the table for the corresponding type of insulation.

Currents Taken by Various Receiving Devices. — The current taken by each receiving device if not stated in the specifications may be determined roughly from the following tables.

CURRENT TAKEN BY INCANDESCENT LAMPS AT 114 VOLTS

Candle power	Amperes per lamp		
	Carbon	Gem	Tungsten
16	0.5	0.35	....
20	....	....	0.22
32	1.0	0.7	....
48	....	....	0.53
50	1.4	1.1	....
80	....	....	0.88
100	2.7	2.2	....

CURRENT TAKEN BY ORDINARY ARC LAMPS

½-inch carbons

Type	Multiple*		Series	
	Volts	Amperes	Volts per lamp	Amperes
Direct current	110	5 to 6.5	70	5 to 6.6
	220	3		
Alternating current	110	6 to 8.5	70	6.6 to 7.5
	220	6		

* On multiple-arc lamp circuits, the conductors must be designed to carry 150 per cent of the normal current taken by the lamps.

CURRENT TAKEN BY DIRECT-CURRENT MOTORS*

Horse-power	Amperes at		
	110 volts	220 volts	500 volts
½	4.5	2.2	1
¾	6.8	3.4	1.5
1	9.0	4.5	2

300	1580	790	316

* These are volts between wires; the corresponding volts to neutral are 63.5, 127 and 318, respectively.

CURRENT TAKEN BY HEATING DEVICES

Device	Amperes at	
	110 volts	220 volts
Flatirons, 3-pound	2.3	1.1
Flatirons, 6-pound	5.5	2.7
Water-heaters, pint	3.6	...
Water-heaters, quart	4.5	...
Water-heaters, 2-quart	9.1	4.5
Chafing dishes	5.2	2.6
Coffee percolaters, 3-pint	4.5	...
Toasters	5.5	...
Heating pads	0.5	...
Cigar lighters	0.7	...
Glue pots, 2-quart	0.8	0.4
Luminous radiators	6.8 to 13.6	3.4 to 6.8

Potential Drop. — In most installations the potential drop *per conductor* between service-entrance or switchboard and the farthest receiver is taken as approximately 3 per cent of the *voltage to neutral* at the service-entrance or switchboard. This is equivalent to a *total drop* (both wires) of 3 per cent of the *voltage between* wires in the case of a two-wire direct-current or single-phase system. In three-wire systems the two outside wires are to be regarded as the feeders.

In direct-current or single-phase alternating-current systems the maximum potential drop *per conductor* will then be $0.015 \times 110 = 1.65$ volts for a 110-volt system, 3.3 volts for a 220-volt system, etc. In three-phase systems the potential drop *per conductor* will be $0.03 \times \frac{110}{\sqrt{3}} = 1.91$ volts for a 110-volt system, 3.82 volts for a 220-volt system, etc. In feeders and branch circuits the drop in the feeders is usually made two-thirds and the drop in the branch circuits one-third of the total drop.

Note that in the case of a lamp load the allowable drop of 3 per cent is based on the current corresponding to the *total connected load*, i.e., this is the maximum drop when *all* lamps are burning. In ordinary buildings the actual maximum load is seldom more than one-third the connected load; consequently when the wiring is designed on this basis the voltage at the lamps will seldom be more than 1 per cent lower than the voltage at the service connection.

Calculation of Size of Wire. — Let

I = current per conductor in amperes,
v = allowable potential drop *per conductor* in volts,
l = length of the conductor in feet,*

then the required cross-section of a copper wire in circular mils is

$$A = \frac{KlI}{v}, \tag{1}$$

where K is a factor depending upon the specific resistance of the wire, the size and spacing of the wires, the frequency and the power factor of the receiver. The factor K for alternating-current circuits is therefore not a constant but for preliminary calculations its value for the sizes of wires and spacings (1 to 6 inches) ordinarily used for interior wiring is approximately as given in the following table. The alternating-current values apply to single-phase, 2-phase 4-wire

System	Power factor	Values of K for copper
Direct current.............	....	11*
Alternating current.........	....	....
Lighting load only.......	1.00	11
Lighting and power loads	0.95	12
Lighting and power loads.	0.90	13.5
Power loads............	0.85	15
Power loads............	0.80	17

* This value is practically exact, the others are approximate only.

and 3-phase 3-wire systems at any frequency from 25 to 60 cycles per second. For a direct-current or single-phase 3-wire system proceed as for a 2-wire system, neglecting the presence of the neutral wire; the neutral wire should then be made the same size as each outside wire as thus calculated.

* Note that l is the length of *each conductor;* the total length of wire for a two-wire line is $2l$, for a three-wire line $3l$, etc.

Commercial sizes of wire differ successively by about 25 per cent in the larger sizes and 60 per cent in the smaller sizes; the odd-numbered sizes smaller than No. 1 are not generally manufactured, although No. 3, 5 and 9 are sometimes made. From the table below * select the size of wire corresponding to the calculated area. Unless the calculated area in circular mils agrees very closely with the area of one of the conductors given in the table, the next larger size of wire should be selected.

600–VOLT RUBBER–INSULATED COPPER WIRE
(Single Braid, N.E.C. Standard; Conductivity of Copper, 98 per cent)

Size, B. & S. gage	Cross-section of copper, cir. mils	Over-all diameter, inches	Ohms per 1000 ft. at 68°F.	Pounds per 1000 ft. of insulated wire	Reactance per 1000 ft. of each wire

* More extended wire tables will be found in the articles on *Wires and Cables*.

† Two insulated wires side by side, the insulation of the two wires in contact.

‡ Measured from insulation to insulation, equals distance between centers minus twice the thickness of insulation on either wire.

Check on Calculation of Size of Wire. — Calculation of Actual Potential Drop. — (*See also Alternating Currents.*) From the table, corresponding to the size of wire selected, take

r = the resistance per 1000 feet of conductor,
x = the reactance per 1000 feet of conductor,

and put

l = length of each conductor in feet,
I = amperes per conductor,
V = volts to neutral at receiver,*
$\cos\phi$ = power factor of receiver,

$$R = \frac{rl}{1000} = \text{total resistance per conductor,}$$

$$X = \frac{xl}{1000} = \text{total reactance per conductor.}$$

Then the actual volts drop *per conductor* is

$$v = \sqrt{(V\cos\phi + RI)^2 + (V\sin\phi + XI)^2} - V. \tag{2}$$

To a very close approximation in all ordinary cases this is equal to

$$v = RI\cos\phi\left(1 + \frac{X}{R}\tan\phi\right). \tag{3}$$

If the drop as calculated does not check within a reasonable value with the drop assumed in calculating the size of the wire, select another size of wire and recalculate, etc. This refinement will be found necessary, only in the case of low power factors and when the size of wire as calculated is either exceptionally large or exceptionally small, in which case the values given for the factor K in the formula for A, equation (1), may be in error by a large amount (in limiting cases 50 per cent or more).

In addition to making sure that the drop will be within a reasonable amount, one should also note whether the conductor selected is large enough mechanically and has the proper current-carrying capacity (*see above*), remembering also that the National Electrical Code requires that conductors through which power is supplied to a motor shall have a current-carrying capacity equal to 125 per cent of the full-load current taken by the motor.

Example of Calculation for a D-C. or Single-phase System. — Incandescent lamps taking 0.5 ampere each are supplied with power from a 115-volt 60-cycle service through a set of feeders 200 feet in length which terminate at a cut-out cabinet as shown in Fig. 7. The lamps are grouped in sets of 10 lamps each (only one set is shown) and each set is connected to the cut-out cabinet by branch circuit conductors averaging 25 feet in length. Assuming a total potential drop of 3 volts, the drop per conductor will be 1.5 volts. The drop per conductor in the branch circuit should then be one-third of 1.5 or 0.5 volt and the drop per conductor in the feeder circuit should be two-thirds of 1.5 or

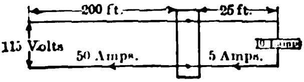

Fig. 7.

* For d-c. or a-c. single-phase or a-c. 2-phase, 2-wire systems $V = \frac{1}{2} \times$ (volts between wires); for a 3-phase system $V = \frac{1}{\sqrt{3}} \times$ (volts between wires); for a 2-phase 3-wire system $V = \frac{1}{2} \times$ (volts between either outside wire and middle wire). In calculating the normal drop in a single-phase 3-wire system pay no attention to the middle wire, i.e. assume a balanced load.

1 volt. The respective calculations of the areas of the conductors in the feeder and branch circuits may then be carried on independently. In the branch circuit, referring to equation (1), $I = 10 \times 0.5 = 5$, $l = 25$ and $v = 0.5$, whence for copper wire

$$A = \frac{11 \times 5 \times 25}{0.5} = 2750 \text{ circular mils.}$$

From the wire table it is found that the next larger commercial size is No. 14 B. & S., which has a resistance of 2.58 ohms per 1000 feet, and a reactance (assuming a 2.5-inch spacing) of 0.106 ohms per 1000 feet.

Referring to equation (3), $V = 57.5$, $\cos\phi = 1$, $\tan\phi = 0$, $R = 2.58 \times 25/1000 = 0.0645$, $X = 0.106 \times 25/1000 = 0.00265$, whence

$$v = 0.0645 \times 5 = 0.323.$$

Equation (2) gives the same value. This voltage is 35.4 per cent less than the assumed voltage of 0.5 volt, but since No. 13 wire is not a commercial size a closer realization of the assumed voltage is impracticable.

In the same manner, the required area of the conductors used in the feeder circuit is determined by substituting the following values in equation (1): $I = 100 \times 0.5 = 50$ amperes, $l = 200$ feet, and $v = 1$ volt. Hence

$$A = \frac{11 \times 50 \times 200}{1} = 110{,}000 \text{ circular mils.}$$

From the wire table it is found that a No. 00 B. & S. wire must be used.

The above calculations although made for a lighting load apply equally well to a motor load, except that in the final selection a wire must be chosen which will carry 125 per cent of the full-load current of the motor.

Example of Calculation for a Three-phase System. — Power is to be supplied by three feeders each 400 feet in length to a three-phase, 60-cycle, alternating-current motor (power factor 80 per cent), the voltage between any two line wires at the service entrance being 550 volts. At full load the current taken by the motor is 50 amperes. The voltage to neutral at the service entrance is $\frac{550}{\sqrt{3}}$ or 318 volts. The wires are to be spaced 6 inches apart.

Allowing a drop in each conductor of 3 per cent of the voltage to neutral, the drop will be 3 per cent of 318 or 10 volts approximately. The following values should then be substituted in equation (1): $K = 17$, $I = 50$ amperes, $l = 400$ feet and $v = 10$ volts, giving

$$A = \frac{17 \times 50 \times 400}{10} = 34{,}000 \text{ circular mils.}$$

From the wire table it is found that a No. 5 B. & S. wire might be used considering the potential drop alone but since the carrying capacity of the conductor must be 1.25×50 or 62.5 amperes, it would be necessary to use a No. 4 wire.

Adopting a No. 4 wire and referring to equation (3), $V = 318$, $\cos\phi = 0.8$, $\tan\phi = 0.75$, $R = 0.253 \times 400/1000 = 0.101$, $X = 0.101 \times 400/1000 = 0.040$, whence

$$v = 0.101 \times 50 \times 0.8 \left(1 + \frac{0.04 \times 0.75}{0.101}\right) = 5.3 \text{ volts,}$$

which is a little more than half the allowable drop of 10 volts. Equation (2) also gives 5.3 volts.

AUTHORITIES GOVERNING THE INSTALLATION OF WIRING IN BUILDINGS. — As noted at the beginning of this article all interior wiring must be installed in accordance with the regulations of the authorities having jurisdiction over the building in question. In general, these authorities are: (1) the fire underwriters; (2) the municipal authorities; and (3) the power company supplying the current.

National Electrical Code. — This code is a set of instructions published in odd years by the National Board of Fire Underwriters. A List of Electrical Fittings approved by the Underwriters' Laboratories, Inc. is published by the National Board in April and October of each year. In order that fire insurance on any building wired for electric light or power may be obtained from an insurance company, the wiring must be installed in accordance with the rules of the National Electrical Code or such modifications of it as are required by law in certain municipalities (*see Municipal Regulation, below*). Permission must also be obtained to use any fitting not included in the list of approved fittings.

Both the Code and the List of Approved Fittings may be obtained gratis by applying to the National Board of Fire Underwriters, 135 William St., New York City. In view of this fact, and the frequent revisions of the rules and list it is not deemed advisable to give them in detail here. The general requirements, however, are covered in the section below on *Methods of Installing Wiring.*

Municipal Inspection. — Many state legislatures have passed laws regulating the installation of electric wiring and empowering the appointment of municipal inspectors of wiring. In some states fines are imposed by legislative enactment upon those who violate the inspector's rules. Although free to decide upon the proper installation of electric wires, municipal inspectors have generally adopted the National Electrical Code as a standard with modifications suited to their desires. A copy of these modified rules can usually be obtained gratis from the municipal authorities.

Regulations of the Light and Power Companies. — The National Electrical Code is usually adopted by electric power companies with the addition of specific requirements pertaining to service connections, placing of meters, type of system, etc.

METHODS OF INSTALLING WIRING. — The National Electrical Code approves the use of the following methods of wiring: open work, moulding (wooden and metallic), concealed knob and tube work, rigid conduit, flexible conduit, armored cable and flexible tubing (in short runs). These methods are described in detail below, but first are given the more important general requirements regarding joints, protection, cut-outs, switches, etc., which apply to all classes of wiring.

General Requirements. — All joints must be mechanically and electrically secure without solder and unless made with some form of approved splicing device must be soldered and covered with an insulation equal to that on the conductor. Wires must be separated from contact with walls, floors, timbers or partitions through which they may pass by non-combustible, non-absorptive insulating tubes, such as glass or porcelain, except at outlets where flexible tubing is required. Unless inclosed in conduit or moulding, wires must be separated from any conducting material or from any other electric wire not more than two inches away by some continuous and firmly fixed non-conductor creating a permanent separation. In damp places wires must be separated from pipes by an air space and should be run over rather than under pipes upon which

moisture may gather. Wires must be protected from mechanical injury by running-boards or guard-strips on low ceilings and by wooden boxing or metal conduit on side walls. Protection on side walls must extend not less than five feet from the floor. No method other than open wiring may be used when the difference of potential between any two wires exceeds 550 volts.

Automatic Cut-outs (fuses or circuit breakers) must be placed in all service wires (i.e., the leading-in wires from the street circuit), and at every point where a change is made in the size of wire unless the cut-out in the larger wire will protect the smaller wire. The cut-out in the neutral of a three-wire system may be omitted if the neutral wire is grounded and is of the same size as the outside wires. No set of incandescent lamps requiring more than 660 watts, whether grouped on one fixture or on several fixtures must be dependent upon one cut-out. Cut-outs must in general be inclosed in an approved cabinet although circuit breakers and inclosed fuses may be placed in plain sight in dry places where there is no danger of igniting any combustible material.

Switches which disconnect *all* wires (i.e., switches having 2, 3 or more poles) must be placed in the service wires as near as possible to the point where they enter the building and in all circuits supplying current to motors, heating devices or lamps; except that in the case of motors of one-fourth horse-power or less in circuits where the voltage does not exceed 300 volts, and in circuits supplying not more than 660 watts of power to heating devices or lamps, single-pole switches may be used in two-wire systems or branches. Switches must always be placed in dry, accessible places and must be grouped as far as possible. When used in rooms where combustible flyings are liable to exist, switches must be placed in dust-tight cabinets and when flush switches are used, they must be inclosed in an approved steel box.

Open Wiring. — When the appearance of the wiring is not important, exposed surface wiring supported on cleats or insulators furnishes one of the safest and best methods of wiring. The wires must be insulated in dry places with rubber, slow-burning weatherproof or slow-burning insulation, in damp places with rubber insulation, and in locations where the wires are exposed to corrosive vapors with weatherproof or rubber insulation.

Voltage	Inches from surface to insulation on wire		Inches between wires* from insulation to insulation
	Dry	Damp	
0–300	0.5	1	2.5
301–550	1	1	4

* In the case of 3-wire d-c. or single-phase systems the neutral may be placed between the two outers, these latter being 2.5 inches apart.

Spacing of Wires and Supports. — Wires must be separated from each other and spaced from the surface wired over as given in the accompanying table.

Wires must be supported under ordinary conditions at least every 4.5 feet, except that in mill construction, wires of not less than No. 8 B. & S. gage, if separated about six inches, may be run from timber to timber and be supported at each timber only. Open wiring cannot be used in elevator shafts.

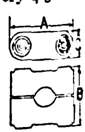

Fig. 8

Cleats. — Cleats are made in a variety of forms. The following are the dimensions and costs of cleats of the form shown in Fig. 8, all dimensions being in inches.

DIMENSIONS AND COSTS OF CLEATS

Size of wire, cir. mils or B. & S. gage	1-wire cleats				
	Dimensions, inches			Size of screw, inches	Cost* per 100
	A	*B*	*C*		
14-12	2	$1\frac{1}{4}$	$\frac{3}{4}$	3×8	$2.50
10- 8	2	$1\frac{5}{8}$	$\frac{3}{4}$	3×8	2.90
6- 3	$2\frac{1}{4}$	$1\frac{3}{4}$	1	3×10	3.15
2	$2\frac{1}{2}$	$1\frac{3}{4}$	$1\frac{1}{8}$	$3\frac{1}{2}$×12	3.40
1-0	$2\frac{1}{2}$	2	$1\frac{1}{8}$	$3\frac{1}{2}$×12	3.90

Wooden Moulding. — When exposed wiring is not desired, and when it is impracticable in old buildings or too expensive in new buildings to install concealed wiring, wooden moulding may be used, provided the difference of potential between any two wires in the same moulding does not exceed 300 volts. Its use is forbidden in elevator shafts and in concealed or damp places. Wooden moulding is manufactured in the following sizes. See table on next page.

Moulding may be made inconspicuous by matching the wood of the moulding to the finish of the room and by using a capping, which will conceal the purpose of the moulding. In this manner, moulding may be made to simulate picture moulding, and on ceilings a panel effect can be obtained by the use of dead moulding. All wires used in wooden moulding must have a rubber insulation and must not be jointed or tapped in the moulding. Branch taps may be made with tap fittings designed for the purpose. Many other moulding fittings are manufactured, which, if used, reduce the labor of installation and improve the general appearance of the work. Wooden moulding is fastened to walls by means of thin screws or toggle-bolts and the capping is nailed on with brads. "Kicking boxes" are usually placed around the end of moulding on floors to protect the wires and porcelain tubes from possible injury.

Metallic Moulding. — Metallic moulding may also be used to conceal and protect wires when the difference of potential between any two wires in the moulding is not more than 300 volts and the power transmitted through the wires contained in the moulding does not exceed 1320 watts. Metallic moulding is manufactured in one width only, namely, 1 inch wide by ⅜ to ½ inch deep, the depth depending upon the type of moulding. The two types of metal

STANDARD WOODEN MOULDING

* Based on purchase price (1913) of large quantities, screws included.

moulding in common use differ principally in the method of attaching the capping. In the "Lutz" metal moulding the capping consists of a flexible metal strip, which is slid into the two grooves that form the upper edge of the moulding. In the "National" metal moulding the capping is snapped over the base. "Lutz" moulding is made in 10-foot lengths while the National moulding is made in 8-foot 4-inch lengths. "Lutz" moulding is listed at $6.50 per 100 feet and "National" moulding at $8.00 per 100 feet, with discounts of about 40 per cent for large quantities.

Metallic moulding cannot be used in concealed or damp places except that, in passing through a floor, such moulding may be used if carried through an iron pipe extending from the ceiling below up through the floor to a point five feet above the floor or to a point at least three inches above the floor where appearance is an essential feature. All parts of a metallic moulding system including outlet boxes, junction boxes and cabinets must be electrically connected and grounded. Fittings employed with metallic moulding must be so constructed as to protect the insulation of the wires from abrasion. Wires placed in metallic moulding must be insulated and installed as in wooden moulding with the exception that in alternating-current systems wires of the same circuit must be installed in the same moulding. It is suggested that this also be done for direct-current systems when there is a possibility that an alternating-current system may be used at some future time.

Concealed Knob and Tube Work. — This method of wiring is forbidden by the inspectors in many large cities, but when approved, it is employed in buildings of frame construction when it is desired to install the wiring at a minimum first cost. The wires when running parallel to beams or studding are supported on knobs and when running through beams, studding or floors are insulated by porcelain tubes. When passing through floors at the bottom of plastered partitions or through braces, the porcelain tubes insulating the wires must project at least four inches above the floor or brace. Split knobs must be used for the support of conductors smaller than No. 8 B. & S. gage except at the end of runs where a solid knob or strain insulator must be used. For conductors larger than No. 8 B. & S. gage, solid knobs may be used. Wires must have a rubber insulation and tie wires when used must have an insulation equal to that of the conductors they confine.

Distance between Wires. — Wires must be installed in such a manner that the distance between *any* two wires is at least 5 inches and each wire must be separated from the surface wired over by a distance of at least 1 inch. If, in any place, the 5 inch separation cannot be maintained, each wire must be separately incased in a continuous length of approved flexible tubing. At outlets, wires must be protected by flexible tubing extending in continuous lengths from the last porcelain support to at least 1 inch beyond the outlet.

Distance between Supports. — Wires must be supported under ordinary conditions every 4.5 feet and if the wires are liable to be disturbed the distance between the supports must be shortened.

Knobs and Tubes. — Two types of knobs are used, namely, the solid knob and split knob. The following table gives the dimensions and costs of one type of split knobs and 4-inch tubes.

Size of wire, B. & S. gage	Split knobs *			Tubes		
	Height, inches	Diameter, inches	Cost † per 100	Inside diameter, inches	Outside diameter, inches	Cost † per 100
14-5	$1\frac{7}{8}$	$1\frac{1}{8}$-$1\frac{1}{2}$	$1.50	$\frac{5}{16}$	$\frac{9}{16}$	$0.70
4-00	2	2	2.00	$\frac{3}{8}$	$\frac{11}{16}$	0.75
				$\frac{5}{8}$	$\frac{15}{16}$	0.85
				$\frac{3}{4}$	$1\frac{3}{16}$	1.00

* Holding single wire 1 inch away from wall.
† Based on purchase price (1913) of large quantities; screws included in cost of knobs.

Rigid Conduit. — Although the most expensive method, rigid conduit is considered to be the the best method of wiring and its use is required by inspectors in certain districts of many large cities. Two kinds of conduit are manufactured; lined conduit, having a lining of insulating material and unlined conduit, having an inner coating of insulating enamel. Unlined conduit is used more often than lined conduit because unlined conduit is cheaper to buy and to install and because wires are drawn in unlined conduit more easily than in lined conduit. In lined conduit corrosive action on the conductors due to a possible leak in the conduit is prevented by the insulating lining. The conductors used in lined conduit cost slightly less than the conductors used in unlined conduit, because the conductors used in unlined conduit must have an

additional layer of braid to allow for abrasion in drawing in the wires. Rigid conduit is manufactured in the following sizes:

STANDARD RIGID CONDUIT

Made in 10-foot lengths

Standard size of pipe, inches	Internal diameter, inches	External diameter, inches	Nominal weight per 100 feet, lb.	No. of threads per in. of screw	Cost * per 100 feet	Max. size of double-braided wire used in a single conduit, B. & S. gage or cir. mils

* Based on purchase price (1913) of large quantities.

Bushings, Bends, etc., in Rigid Conduit. — All parts of the conduit system including outlet or junction boxes must be mechanically secured in place and must be electrically connected and grounded. At outlets or junction boxes rigid conduits must be provided with bushings or nipples to protect the wires from abrasion. The radius of curvature of the inner edge of an elbow or bend must not be less than 3.5 inches and there must not be more than the equivalent of 4 quarter bends from outlet to outlet, the bends at the outlet not being counted. Bends should be used whenever possible in place of elbows as the wires will pass more easily around a bend than an elbow. The various bending tools that are on the market consist of some form of lever, the end of which may be slipped over the conduit while it is in position. When the number of bends between outlets becomes excessive or when a large number of conduits placed side by side must be deflected, pull boxes are installed so that the direction of the conduit may be changed and the wires may be drawn in more easily. In fireproof buildings conduit is frequently installed just after the steel work has been erected and is then covered up by concrete or tiling.

Insulation of Wires Used in Rigid Conduits. — Wires used in rigid conduit must have an approved rubber insulation and must not be spliced or tapped within the conduit. In alternating-current systems the two or more wires of a circuit must be drawn in the same conduit. It is suggested that this be done for direct-current systems also when there is a possibility that an alternating-current system may be used at some future time. The same conduit must not contain more than four two-wire or three three-wire circuits of the same system and circuits of different systems must be run in separate conduits.

Wires should not be drawn in until all mechanical work on the building has been completed. For short runs wires may be pushed in at one opening until they come out at the other opening, but on long runs or where there are many bends, a spring-steel "fish-wire" or "snake" is first pushed through the conduit and a piece of sash cord attached to the "fish-wire" is pulled through. The

conductor is then attached to the sash cord and pulled through. When the wires cannot be pulled through a conduit easily, powdered soapstone is blown into the conduit to reduce the friction of the conductors.

Supports for Wires. — In vertical runs conductors must be supported in the conduit in accordance with the following table:

No. 14 B. & S. to 0.	every	100	feet
No. 00 B. & S. to 0000,	"	80	"
0000 B. & S. to 350,000 cir. mils,	"	60	"
350,000 cir. mils to 500,000 cir. mils,	"	50	"
500,000 cir. mils to 750,000 cir. mils,	"	40	"
750,000 cir. mils,	"	35	"

Conductors may be supported by a turn of 90 degrees in the conduit system or by junction boxes designed for the purpose.

Flexible Conduit. — In distinction to flexible tubing, a non-metallic tubing, flexible conduit is a *metallic* tubing built up of spiral, convex and concave steel strips which interlock in such a manner as to form a fairly smooth surface, externally and internally. "Flexible conduit," which is metallic, is usually distinguished from "flexible tubing" (*see below*), which is non-metallic tubing. Flexible conduit possesses the advantage over rigid conduit in that it can be installed continuously and quickly from outlet to outlet and if necessary may be fished between partitions or floors. Its chief disadvantages are that it is neither nail-proof nor moisture-proof. Flexible conduit is manufactured in the following sizes:

STANDARD FLEXIBLE CONDUIT

Size, inches	Approx. outside diameter, inches	Weight per 100 feet, pounds	Approx. feet in coil	Cost * per 100 feet	Max. size of double-braided wire used in single conduit, B. & S. gage or cir. mils		
					1 wire	2 wire	3 wire
5/16	0.485	20	250	$2.65	14	......	......

2	2.56	265	25-50	30.00	800,000	200,000	00

* Based upon purchase (1913) of large quantities.

All requirements as to installation and wires used in rigid conduit apply as well to flexible conduit.

Armored Cable. — In place of flexible conduit in which wires must be drawn in after the conduit is installed, armored cable consisting of rubber-insulated conductors protected by interlocking spiral steel strips may be used. When installed in damp places, leaded armored cable, which has a lead covering between the insulation and the steel armor, must be used. Armored cable is employed extensively in wiring old buildings where it would be impossible to install rigid conduit without cutting up the walls and floors. Armored cable for interior wiring is manufactured in the following sizes:

STANDARD ARMORED CONDUCTORS

Size of each conductor, B. & S.	Number of bunched conductors		Approx. outside diameter, inches	Weight per 100 feet, pounds	Approx. feet in coil	Cost,† per 100 feet
14	1	Steel armored	0.37	20	250	$3.85

10	2		0.861	108	100–150	16.00
8*	2		0.900	125	100–150	20.50
14	3	Steel armored	0.648	53	150–250	8.70
12	3		0.675	55	150–250	10.70
10	3		0.755	66	100–200	14.80
8*	3		0.900	99	100–150	20.50
14	3	Lead covered and steel armored	0.694	79	100–150	14.00
12	3		0.766	88	100–150	16.20
10	3		0.901	117	100–150	18.40

* Stranded. † Based on purchase price (in 1913) of large quantities.

All requirements as to mechanical and electrical connections to outlet boxes, grounding, splicing and tapping of wires, assembling of conductors in alternating-current systems, etc., applying to rigid conduit also pertain to armored cable. Bends in armored cable may be of smaller radius than in rigid conduit, however, the minimum allowable radius of a bend being 1.5 inches for armored cable.

Flexible Tubing. — In addition to its use in all places where it is necessary to add to the insulation of the conductors, if the difference of potential between the wires is not over 300 volts, continuous flexible tubing may be used to protect individual wires when fished for short distances in dry places. Although not allowed by some inspectors, flexible tubing is extensively used in this manner in conjunction with moulding or knob and tube work, especially in old buildings where it is necessary to fish the wires to avoid cutting into walls, floors or ceiling. Flexible tubing is manufactured in the following sizes:

STANDARD FLEXIBLE TUBING

Inside diameter, inches	Feet in coil	Weight per 1000 feet, pounds	Cost per 100 feet	Largest size of wire accommodated, B. & S.
1/4	250	75	$1.65	14

1 3/4	100	440	12.70	600,000
2	Odd lengths	600	14.90	800,000
2 1/4	Odd lengths	700	17.60	1,100,000

COST OF WIRING. — The total cost of wiring a building is made up of the three elements: materials, labor and engineering. The labor and engineering charge will depend upon local conditions, and these costs may be estimated accurately only by reference to similar costs in completed work of the same general character. In regard to labor, the local conditions must include the factor of wages paid in the vicinity and the amount of work completed in a given time by the class of labor available. In determining the engineering charge the contractor must estimate the amount for each contract which should be charged to office expense and solicitation of business.

Office Estimates. — The cost of the materials is usually determined from a supply catalogue; approximate costs of moulding, cleats, conduits, etc., are given above. This may be accomplished by finding (1) the costs of the wiring materials between outlets and (2) the costs of the special devices such as outlet boxes, switches, cut-out cabinets, etc., and adding the two together.

Cost of Rubber-covered Copper Wire. — The cost of insulated wire depends upon (1) the cost of copper-wire bars, (2) the cost of rubber gum, (3) the cost of the other ingredients in the insulation, and (4) upon the cost of manufacture. Items 1, 2 and 3 are subject to considerable variation from year to year, and consequently any costs given at the present time must be used with caution at any later time. In Table A is given the present (1913) cost of rubber-

insulated copper wire (*National Electrical Code Standard*) on the basis of copper at 15 cents per pound, together with the amount by which these costs must be increased or decreased for each cent increase or decrease in the cost of copper, assuming all other items unchanged in cost.

Cost of Wiring Material per 100 Feet of Single Wire. — Tables B and C give the cost of all wiring material, exclusive of insulated wire, switches, cut-outs, etc., per 100 feet of *single* wire for all methods of wiring. Table D gives approximate costs of switches, cut-outs, etc. Costs of armored conductors are given above.

The costs are based upon the purchase price (1913) of large quantities.

TABLE A. — COST OF ONE HUNDRED FEET OF RUBBER-COVERED COPPER WIRE

Example of Use of Tables. — A three-phase, 550-volt, 25-horse-power, 80-per-cent power-factor induction motor is to be connected to a switchboard by conductors drawn in rigid conduit, the length of the conduit being 250 feet. The current taken by the motor is approximately 28 amperes. Assuming a potential drop in each conductor equal to 3 per cent of the voltage to neutral, the drop will be 9.5 volts per conductor. From equation (1), the required cross-section is then $A = 12,500$ circular mils. From the table of current-carrying capacity (see above), the corresponding size of wire which will carry 1.25×28 or 35 amperes is a No. 8. Assuming the base price of copper to be 14 cents per pound;

From table A, 100 feet of solid No. 8 wire costs 1.98–0.05 =	$1.93
Add for double braid	0.40
From table C, 100 feet of conduit costs per wire	2.56
Total cost per 100 feet of each wire	$4.89

Cost of 250 feet and for three wires is $\$4.89 \times 2.5 \times 3 = \$36.60$. To this **amount must be added the cost of switches, cut-outs, etc., labor and engineering.**

TABLE C.—COST OF WIRING MATERIAL PER 100 FEET OF SINGLE WIRE

Exclusive of Wire, Cut-Outs, Switches, Receptacles, Etc.

Size of wire, cir. mils or B. & S.	Flexible tubing containing 1 wire	Rigid conduit containing		Flexible conduit containing

TABLE D.—APPROXIMATE COST OF "HARDWARE"

	Each
Switches:	
Flush push button, single pole	$1.00
Standard snap, single pole	0.50
Automatic door switch	1.50
3-way flush switch	1.10
3-way snap switch	0.50
Cut-Outs:	
Standard double pole	0.12
3- to 2-wire double-branch	0.26
Receptacles:	
Waterproof floor receptacle	3.00
Flush baseboard receptacle	1.50
Standard wall socket	0.50
Drop cords:	
Drop cords, including spun brass canopy, cord and socket	1.00
Drop cord (without canopy)	0.75

Field Estimates. — In order to enable its representative to make a rapid estimate of the cost of wiring a building while he is interviewing the owner or agent, the contract department of a lighting company usually provides their solicitors with a schedule of wiring costs, based (1) upon the number of lamp sockets and *switch* outlets to be provided, or (2) upon the *total* number of outlets (both lamp and switch), or (3) upon the number of lamp sockets and the number of *lamp* outlets required. Such wiring schedules are usually applicable only to finished buildings; the cost of wiring a building while it is being erected is usually much less than the cost of wiring the same building after it has been completed.

First Method. — The buildings to be wired are divided into classes and the cost of wiring a building in any class is based upon the number of lamp sockets, the number of *switch* outlets, and the type of switches and receptacles installed. The disadvantage of this method is that it does not take into account the number of lamp outlets. In two buildings in which the same number of lamp sockets are installed, the number of lamp outlets may differ widely, and as a result the labor and material required for the work will differ in the two buildings although the cost of the wiring *may* be the same. In most instances, however, this defect is not serious, because of the close relationship between the number of lamp sockets and the number of lamp outlets which are usually installed in the buildings for which the schedule is intended.

Second Method. — The various openings for switches, receptacles, drop cords and fixtures are considered as outlets and on the number of these is based the cost of work in houses of different classes of construction. An extra charge is made for hardware and for work installed under double or hardwood floors. With this method the number of lamp sockets installed in two houses for which the cost of wiring is the same may differ considerably. For schedule of cost see *Elec. World, 1910, Vol. 56, p. 1131.*

Third Method. — The buildings to be wired are divided into classes and the cost of wiring a building in any class is based upon the number of lamp outlets and lamp sockets and the type of switches installed. This method is an improvement on Methods I and II as it does take into account the average number of lamp sockets per lamp outlet, and while the cost of the wiring in two buildings requiring the same labor and material may differ slightly, such differences will not be as frequently encountered as in the other two methods. As an example of this type of schedule see article in *Elec. World, 1912, Vol. 59, p. 548,* descriptive of the method used by the Consolidated Gas, Electric Light and Power Company of Baltimore, Md.

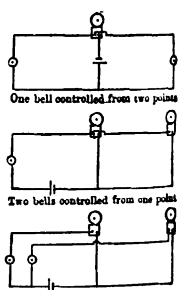
[R. G. HUDSON.]

WIRING OF BUILDINGS FOR MISCELLANEOUS DEVICES. — (*See also Wiring of Buildings for Light and Power.*) In addition to the wires designed to conduct electrical energy to lamps, motors and heating devices in a building, wires may be installed in connection with telephone (q.v.), telegraph (q.v.), district messenger and call-bell circuits, fire and burglar alarms, door-opening devices, gas lighters, watchman's clocks and electric clocks. Since all of these devices are operated at low voltage, it is unnecessary to use the same care in selecting and installing the wires as in the higher voltage systems, except that in all low-voltage systems care must be exercised that the conductors shall not become crossed with light and power circuits.

Protection of Low-voltage Wiring. — When the conductors of any low-voltage system are brought into a building from the outside, an approved protective device must be located as near as possible to the entrance of the wires to the building. With the exception of instrument circuits of telegraph systems, where cut-outs only are required, protective devices must contain a lightning arrester with a ground connection and a cut-out or heat-coil (*see Telephone Instruments and Circuits*). The conductors beyond the protective device in low-voltage systems need be insulated only sufficiently to prevent short-circuits and the consequent interruption of service. When bunched together in vertical runs the wires must be inclosed in a fire-resisting covering to prevent the wires from carrying fire from floor to floor. Low-voltage circuits may be run in the same shaft with light and power circuits, provided the two classes of wires are separated by at least two inches or one of the classes is run in a non-combustible tubing. Low-voltage wires may not be run in any case in the same tube with lighting or power wires.

Telephone Wiring. — (*See also Telephone Instruments and Circuits.*) Except in large buildings, rubber-insulated twisted pairs of wire are used extensively for telephone work. The twisted wires may be fished between partitions or concealed in moulding and if open wiring is not objectionable, the wires are carried along the finish of the room and fastened with insulating staples or tacks. In new buildings the wires are frequently installed in conduit and local connections are made at connection boxes designed for the purpose. In large buildings, when the number of telephones in use becomes very great, lead-covered insulated cable containing multiple pairs of conductors is installed in wire-ways provided for the purpose. Distributing connection boxes to which branch circuits may be connected are then installed on each floor.



One bell controlled from two points

Two bells controlled from one point

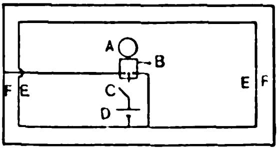
Selective ringing

Fig. 1.

Bell Wiring. — In its simplest form a bell-wiring system consists of a battery (usually a Leclanché type or dry battery), a bell-push, a bell or buzzer and the connecting wire. Paraffine-impregnated double-cotton covered wires ranging in size from No. 16 to No. 22 B. & S. gage are usually employed, either singly or in the form of twin wires. The wires may be fished, concealed in moulding or run exposed along the finish of the room. When a large number of bell-wires must be run together through a building as in the case of a hotel annunciator system, the wires are frequently inclosed in a cotton braid or in a tube made of zinc or impregnated paper. In many buildings supplied with an alternating current source of power a small step-down transformer is used in place of the batteries, thus effecting a saving in the cost of the installation and eliminating the possibility of run-down bat-

teries. In Fig. 1 are shown several systems of bell wiring; these figures are self-explanatory.

Burglar Alarms. — In place of the bell-push used in bell-wiring systems, the bell circuit may be closed by some circuit-closing device attached to windows, doors, etc., so that the opening of any window or door in the building will be made known by the ringing of a bell. As such a system has the objection that it will not operate if the battery is run down or if the wires are cut, a closed-circuit system is preferable, in which the opening of a window or door opens the circuit



A Bell B Constant Ringing Drop

Fig. 3. Closed-circuit Burglar Alarm

and a relay in turn closes the bell circuit. In Fig. 2 is shown a typical open circuit and in Fig. 3 a typical closed-circuit system. In Fig. 4 are shown a door spring *A* and a window spring *B*.

Fire Alarms. — In the manually-operated system glass disks are placed at convenient points throughout the building and with each disk is provided a hammer, with which the disk may be broken in case of fire. The breaking of the disk opens or closes an electric circuit by means of which electric gongs are rung throughout the building. In the automatic system the expansion or fusion by heat of elements in circuit-closing or opening devices usually placed on ceilings, causes gongs to ring throughout the building or in the watchman's office.

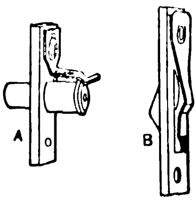

Fig. 4.

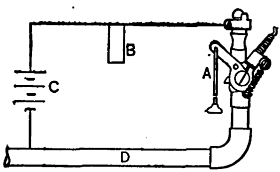
Door-opening Devices and Electric Clocks. — Doors may be opened by pressing a button at some distant point and thereby closing a circuit, through which current flows, energizing a magnet, which releases the nosing in the door frame. In the same manner, a moving disk on a master clock may periodically close a circuit, through which a magnet is energized which operates a pawl attached to the hands of another clock.

Watchman's Clock. — Circuit-closing devices are placed at different points throughout a building so that a watchman on his rounds may close the circuit by means of a handle or special key. The closing of the circuit at any station makes a record on a dial in the watchman's clock indicating the time at which the circuit was closed at each particular station, the stations being designated by numbers. To obviate the possibility of run-down batteries, magneto systems are often installed, a small magneto being placed at each station.

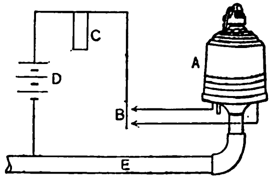
Gas Lighters. — In the "pull-burner" and "automatic-burner" systems, when the gas is turned on, an electric circuit is made and broken by means of contacts placed at the tip of the burner. To intensify the spark at the burner, a spark coil is always connected in series with the circuit. In the "pull-burner" system (Fig. 5) the pulling of a chain or the turning of a key on the gas jet turns on the gas and at the same instant makes and breaks the circuit by contacts

placed near the burner. In this system one wire connects the battery in series with a spark coil to the contact device, the other terminal of the contact device being grounded to the gas pipe through which connection is made to the other terminal of the battery.



A Pull Burner
B Spark Coil
C Battery
D Gas Pipe

Fig. 5.



A Automatic Burner
B Two-Button Push
C Spark Coil
D Battery
E Gas Pipe

Fig. 6.

In the "automatic-burner" system (Fig. 6) three wires are run from a two-button push to one pole of the battery and one terminal each of the two magnets on the automatic burner, the other terminals of the battery and the two magnets being grounded on the gas pipe. The two push buttons are usually made black and white respectively, the white button being pushed to light the gas and the black one to extinguish it. When the white button is pushed, a circuit is closed connecting the battery, the magnet which turns on the gas, the vibrating contactor and the spark coil in series. When the black button is pushed, a circuit is closed connecting the battery and the magnet, which turns off the gas, in series.

[R. G. HUDSON.]

X-RAYS. — (*See also Generators, Static; Induction Coils.*) X-rays or Röntgen rays are generated when the cathode rays of a vacuum tube impinge upon any solid substance. The form of X ray tube commonly used, known as a "focus tube," is shown in Fig. 1. When a high unidirectional e.m.f. is impressed between the anode (*A*) and the cathode (*C*), the cathode rays emitted from (*C*) strike upon the anti-cathode (*B*) from which the X-rays originate. The anode and cathode are made of aluminum because of its low rate of disintegration under vacuous discharge. The anti-cathode is made of platinum to withstand the intense heat of cathodic bombardment. The anti-cathode must be electrically connected to the anode to prevent the possible emanation of cathode rays from its surface. The cathode is concaved spherically so that its rays are focussed upon the anti-cathode, the rays falling within a spot not more than 0.08 inch in diameter. Owing to the repulsion between the particles constituting the cathode rays, the optical focus point of the cathode should fall just in front of the surface of the anti-cathode, so that the actual focus point will fall upon the surface of the anti-cathode. The vacuum tube, made of thin glass to reduce the absorption of the X-rays, is blown in spherical form to withstand the external pressure most effectively.

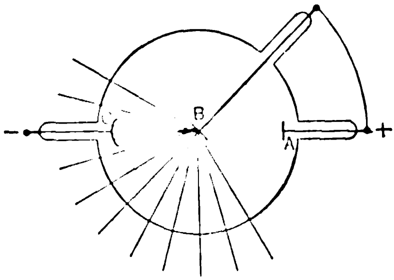

Fig. 1. X-ray Tube

Character of X-Rays. — Numerous attempts made to prove that X-rays are of undulatory form, similar to that of light, have been unsuccessful. It has been found that X-rays are neither reflected nor refracted and are not deflected like cathode rays by a magnetic force. Barkla (*Phil. Trans., 1905, p. 467*) found that such rays may be polarized and his conclusions have been confirmed by other investigators. According to the existing information, it may only be presumed that, when the negatively electrified particles constituting the cathode rays strike any solid substance, they lose their charge and give rise to the extremely high vibrations known as X-rays. It has been shown that such rays do not emanate from the impact spot on the anti-cathode but from a ring surrounding the spot, and travel in all directions from the surface of the anti-cathode, the densest emanation being in a direction normal to the surface.

Properties of X-Rays. — All substances, many of which are opaque to ordinary light, transmit X-rays to a greater or less degree. In most cases the transparency of any substance to such rays is (roughly) inversely proportional to its specific gravity. In the accompanying table are given the relative transparencies of various substances and their specific gravities, the transparency of water being taken as unity.

When X-rays are passed through gases, the gases become ionized and their electrical conductivity is accordingly increased. This property has been used as a means of measuring the relative strengths of X-rays.

Certain substances fluoresce under the action of X-rays making the existence of X-rays visible to the eye. The fluorescent screens ordinarily used for anatomical examinations are coated with barium platino-cyanide, potassium platino-cyanide or calcium tungstate.

X-rays are to a considerable degree chemically active and photographs may be made of objects generally opaque to the eye but built up of substances of

TRANSPARENCY OF VARIOUS SUBSTANCES TO X-RAYS

Platinum	22.07	0.020

different transparencies to the X-rays, so that the internal structure of the object is revealed in the photograph. Such photographs made with highly sensitive plates are called radiographs or skiagraphs.

Considerable use is also made of X-rays in the electro-therapeutic treatment of certain diseases especially those of the skin.

Manipulation of the Tube. — It is important that the tube be connected in the proper polarity as a reverse current in the tube will cause it to blacken. The voltage used with the tube depends upon its size and the degree of vacuum attained. The ordinary tube requires a voltage of from 50,000 to 100,000 volts, or, as usually stated, a voltage which will puncture a needle gap of from 3 to 10 inches in air. The source of e.m.f. used with the tube is usually an induction coil (q.v.) and in some cases a static generator (q.v.). The voltage required to puncture a tube is materially reduced if a sheet of tinfoil electrically connected to the cathode terminal is wrapped around the outside of the tube at the cathode end and covering about one-third of its surface. The current taken by a tube is extremely small so that the connecting wires need only be large enough to withstand breakage but must be heavily insulated. Under continuous use the internal pressure of the gas in the tube decreases due to the occlusion of the gas content by the metals and glass of which the tube is constructed.

As the internal pressure in the tube decreases, it may become inoperative and should then be heated in an oven to release the occluded gases and reestablish the proper pressure. Certain "regenerative" tubes contain palladium which occludes gas at ordinary temperatures and gives off gas under heat, thereby maintaining a constant pressure within the tube.

"Hard" and "Soft" Tubes; Condition of Tubes.—The penetrating power of an X-ray tube is proportional, within certain limits, to its vacuity. A high-vacuum tube, known as a "hard" tube, will emit a few rays of great penetrating power, whereas a low vacuum tube, known as a "soft" tube will emit a greater number of rays of less penetrability. In most cases better contrast is obtained upon the photographic plate or fluorescent screen when a "soft" tube is used than when a "hard" tube is used, since the rays emitted by a "hard" tube may penetrate all the constituent parts of the object examined with nearly equal strength.

The condition of a tube under operation may be easily detected by observing the color of the vacuous discharge. When running under normal conditions, the tube will glow with a greenish-yellow light; the face of the anode will emit a canary-yellow light, but in the space behind the anode, a violet glow will appear. The question of correct polarity may then be checked by this appearance of the anode. A pinkish light within the tube indicates that the vacuum is too low, and the absence of any glow indicates too high a vacuum. A needle gap connected in parallel with the tube will show when the voltage is too high and protects the tube from excessive voltages.
